Abstract

Lexical Semantic Relatedness and Its Application in Natural Language Processing

Alexander Budanitsky

Department of Computer Science

University of Toronto

August 1999

A great variety of Natural Language Processing tasks, from word sense disambiguation to text summarization to speech recognition, rely heavily on the ability to measure *semantic relatedness* or *distance* between words of a natural language. This report is a comprehensive study of recent computational methods of measuring lexical semantic relatedness. A survey of methods, as well as their applications, is presented, and the question of evaluation is addressed both theoretically and experimentally. Application to the specific task of intelligent spelling checking is discussed in detail: the design of a prototype system for the detection and correction of malapropisms (words that are similar in spelling or sound to, but quite different in meaning from, intended words) is described, and results of experiments on using various measures as plug-ins are considered. Suggestions for research directions in the areas of measuring semantic relatedness and intelligent spelling checking are offered.

Acknowledgements

First and foremost, I must thank my academic advisor, Graeme Hirst, for having provided a wealth of ideas, constructive feedback, unfailing support, and overall help in all aspects of this work.

Next in magnitude, I would like to thank Mark Chignell for having taught me everything I know about statistical analysis and Stephen Green for having shared both his programing expertise and his actual code.

A considerable portion of this report draws on work of other researchers. Among them are Reem Al-Halimi, Jay Jiang, Hideki Kozima, Claudia Leacock, Dekang Lin, Manabu Okumura, Philip Resnik, David St-Onge, and Michael Sussna — all of whom I thank personally for having entertained my follow-up queries.

Last, but not least, sincere thanks to Melanie Baljko, Philip Edmonds, Christiane Fellbaum, Sanda Harabagiu, Karen Kukich, and Daniel Marcu for helpful discussions and encouragement.

For financial support, I gratefully acknowledge the Natural Sciences and Engineering Research Council of Canada, the University of Toronto, and the UofT Department of Computer Science.

Chapter 1

Introduction

1.1 Background and Motivation

Is *first* related to *final*? Is *hair* related to *comb*? Is *doctor* related to *hospital* and, if so, is the connection between them stronger than that between *doctor* and *nurse*? In what sense is *virgin* related to *bush*?[1] Striving to provide well-justified answers to these questions are lexical semanticists working in the area of *measuring semantic relatedness*. Their main motivation lies in the tremendous applicability of the ability to measure semantic relatedness to practical tasks involving natural language. In word sense disambiguation, for instance, the intended sense of a polysemous word can be found by computing the semantic relatedness of the word in each of its senses to a window of unambiguous words surrounding it in text and then selecting the sense delivering the highest cumulative value of the relatedness [Sussna, 1993, Sussna, 1997]. To determine the structure of a text, the knowledge of what words are semantically related can be used to identify sequences, or *chains*, of such related words, which can in turn be used to determine boundaries between segments of text that form 'topical units' (*e.g.,* paragraphs in the case of transcribed speech) [Morris and Hirst, 1991, Okumura and Honda, 1994]. If one

[1] We thank Chrysanne DiMarco for suggesting some of these examples.

is furthermore capable of differentiating among word chains on the basis of their *strength*, summaries of a given text can be generated by, for instance, extracting text segments corresponding to the chains stronger than a certain threshold [Barzilay and Elhadad, 1997]. An obvious use of semantic relatedness in information retrieval is as a replacement for the conventionally used lexical equivalence: instead of retrieving documents solely on the basis of occurrence of query terms in them, we could include into consideration documents containing terms that are semantically related to query terms [Cohen and Kjeldsen, 1987, Rada and Bicknell, 1989]. In speech and text recognition, the most likely interpretation of an unrecognizable lexeme can be computed by choosing the candidate most closely related to a subset of the lexemes recognized earlier.

The problem of formalizing and quantifying the intuitive notion of *semantic relatedness* between lexical units has a long history in philosophy, psychology, and artificial intelligence, going back at least to Aristotle (384–322 B.C.E.).

Among the heralds of the contemporary wave of research are Osgood [1952], Quillian [1968], and Collins and Loftus [1975]. Osgood's "semantic differential" was an attempt to represent words as entities in an n-dimensional space, where measuring the distance between them could naturally follow from our knowledge of Euclidean geometry. Unfortunately, after extensive experimentation, Osgood found his system to rely on "connotative emotions" attached to a word rather than its "denotative meaning" [Kozima and Furugori, 1993] and discontinued further research. The more 'procedural' approach of Quillian and Collins and Loftus, termed "spreading activation", on the other hand, continues to motivate researchers in lexical semantics still [Hirst, 1987, Kozima and Furugori, 1993, Kozima and Ito, 1997].

Almost two decades ago, McGill and colleagues [1979] drew up a list of 67 similarity measures used in information retrieval alone [Lin, 1998]. Research in the field has remained active and productive to this day, with the impressive range of applications that the ability to measure semantic relatedness has found being, as we argued above, the

principal driving force behind it.

This report is an attempt to survey the current state of affairs with regard to the methodology for (Chapter 2) and uses of (Chapter 4) measuring semantic relatedness, address the question of assessing the 'goodness' of a computational measure (Chapters 3 and 5), and suggest directions for future research in the area (Chapter 6).

1.2 A Word on Terminology and Notation

When reviewing literature related to the topic of the report, one can notice at least three different terms used by different authors or sometimes interchangeably by same authors: *relatedness, similarity,* and *distance.*

Resnik [1995] attempts to demonstrate the distinction between the first two by way of example. "*Cars* and *gasoline*", he writes, "would seem to be more closely related than, say, *cars* and *bicycles*, but the latter pair are certainly more similar." *Similarity*, thus, represents a special case of *relatedness* — and this is the perspective we adopt in this report. Among other relationships that the notion of *semantic relatedness* encompasses are the various kinds of meronymy (*e.g.,* window–house, issue–serial publication), antonymy (hot–cold), and functional association (ocean–cruiser).

The term *semantic distance* may cause even more confusion, as it can be used when talking about either *similarity* or *relatedness*: two concepts are close to one another if their similarity or relatedness is high, and they are distant in the opposite case. Furthermore, most of the time, the two uses do not contradict each other. But not always: if concepts are close if and only if they are similar, concepts must be distant if they are dissimilar; if, however, similarity is regarded as a generalization of synonymy, then, since antonymy is a special case of dissimilarity, one could argue that the above relation ceases to be intuitive, for antonyms are, actually, very close to each other semantically.

We would thus have very much preferred to be able to adhere to the view of semantic

distance as the inverse of semantic *relatedness*, not merely *similarity*, in the present report. Unfortunately, because of the sheer number of methods measuring *similarity*, as well as those measuring distance as the opposite of *similarity*, this would have made for an awkward presentation. Therefore, more due to tradition than common sense, we have to ask the reader to rely on context when interpreting what exactly the expressions *semantic distance, semantically distant,* and *semantically close* mean in each particular case.

Various approaches presented below speak of *concepts* and *words*. As a means of acknowledging the polysemy of language, in this report, unless stated otherwise, the term *concept* will refer to a particular sense of a given *word*. In running text, examples of concepts are typeset in sans serif whereas examples of words are given in *italics*; and in formulas, concepts and words will usually be denoted by c and w, with various subscripts. For the sake of uniformity of presentation, we have taken the liberty of altering the original notation in some formulas accordingly.

Chapter 2

Recent Approaches to Measuring Semantic Relatedness

2.1 Dictionary-Based Approaches

2.1.1 Background

Dictionaries are perhaps the resource most readily associated with linguistic knowledge in people's minds. It is therefore not at all surprising that attempts have been made to adapt dictionaries to the task of measuring semantic distance computationally.

The *Longman Dictionary of Contemporary English* (LDOCE) was the first dictionary available to researchers in a machine-readable format (on a magnetic tape).[1] The structure of LDOCE, coupled with the cooperation of its publisher, "has made it the most widely used English dictionary for language processing" [Guthrie *et al.*, 1996].

A remarkable feature of LDOCE, exploited in both works presented in this section, is its use of a controlled vocabulary in headword definitions. The *Longman Defining Vocabulary* (LDV) comprises 2,851 words, chosen on the basis of West's [1953] survey of

[1] "In return for a carefully worded contract restricting use to research projects and a moderate sum of money" [Evens, 1988].

restricted vocabulary, and each of the dictionary's 56,000 headwords is defined in terms of these words only.[2]

2.1.2 Kozima and Furugori's Spreading Activation on an English Dictionary

A well-compiled dictionary may be viewed as a "closed paraphrasing system of natural language" [Kozima and Furugori, 1993]: each of its headwords is defined in terms of other headwords and/or their derivatives. A natural way of turning a dictionary into a network is thus to create a node for every headword and link this node to the nodes corresponding to all the headwords encountered in its definition. Having done this, one will immediately notice that, if the dictionary uses a controlled defining vocabulary, it will correspond to the densest part of the network: the remaining nodes, which represent the headwords outside of the defining vocabulary, can be pictured as being situated at the fringe of the network, as they are linked only to defining-vocabulary nodes and not to each other.

These observations and the conforming structure of LDOCE underlie Kozima and Furugori's technique of creating a semantic network from an English dictionary. They began by extracting from LDOCE only those entries whose headwords belonged to the LDV. The resulting *sub*dictionary, rendered as *s*-expressions and named **Glossème**, contained 2,851 entries comprising 101,861 words (tokens) in all. Each entry of Glossème was composed of a *headword*, a *word-class* (part of speech), and one or more *units* corresponding to the numbered sense-definitions in the respective LDOCE entry. Each unit, in turn, consisted of a *head-part*, corresponding to the genus, and one or more *det-parts*, corresponding to the differentia.

Glossème was subsequently translated into a semantic network named **Paradigme**.

[2] The figures are for the 1987 edition of LDOCE, with which both groups of researchers worked.

Paradigme spans 2,851 nodes, corresponding to the entries of Glossème, interconnected by 295,914 unnamed links.

Each node of Paradigme includes a *headword*, a *word-class*, and an *activity-value* (*see* below) and is linked to the nodes representing the words in the definition of the Glossème entry to which it corresponds (for the average of approximately 104 links per node). Links emanating from a given node form two distinct sets: a *référant* and a *référé*. The référant set is meant to be reflective of the *intensions* of the node's headword. It contains several subsets, called *subréférants*, each of which corresponds to a Glossème unit (*i.e.,* its constituent links connect the node to the nodes representing the words in the unit). We can think of a référant as the set of *outgoing* links of a node. The référé of a node n, on the other hand, provides information about its *extension* by linking n to the nodes that refer *to* it (in their respective Glossème definitions). This group of links can thus be viewed as *incoming*.

As a brief illustration, the word *red* gives rise to two nodes in Paradigme: one for its adjective (`red_1`) and the other for its noun senses (`red_2`). Then, `red_1` will have *red* as the headword and *adj* as its word-class. Its second subréférant, corresponding to the unit '(of human hair) of a bright brownish orange or copper colour', will include links to the nodes `brown_1` (note the morphological transformation), `colour_1`, and `colour_2`. Its référé, on the other hand, will include a link to `apple_1`, as the latter has a link to `red_1` in its référant.

Finally, a link to node n has *thickness* t_n, computed from the frequency of its headword w_n in Glossème "and other information" and normalized over each subréférant or référé. (*See* [Kozima and Furugori, 1993] for further details.)

Once the network is built, the similarity between words of the LDV can be computed by means of spreading activation on the network. Each node can hold activity (in its *activity-value* field), which is received and transmitted through network links. Node n's

activity value $v_n(T+1)$ at time $T+1$ is calculated as follows:

$$v_n(T+1) = \phi(\frac{R_n(T) + R'_n(T)}{2} + e_n(T)) \ , \tag{2.1}$$

where $R_n(T)$ and $R'_n(T)$ are the composite activities, at time T, of the nodes referred to in n's référant and référé, respectively,[3] $e_n(T)$ is the activity imparted, at time T, onto n from the outside (*see* below), and ϕ is a function limiting the output value to $[0,1]$.[4]

Activating node n for a period of time t, *i.e.,* letting $e_n(T) > 0$ for $T \in [0,t]$, causes the activity to spread over Paradigme. This results in an *activated pattern*, which, in Kozima and Furugori's estimates, reaches equilibrium after 10 steps (time units). The pattern produced by activity that originates at a given node k can be used to assess the similarity between the node's headword, w_k, and any word in the LDV. The algorithm for computing similarity $\mathrm{sim}_{\mathrm{KF}}(w_k, w_l)$ between the words w_k and w_l is as follows:

1. Reset activity-values of all the nodes in the network.

2. Activate node k, corresponding to the word w_k, with strength $e_k = s(w_k)$ for 10 steps to obtain an activated pattern $P(w_k)$. Here, $s(w_k)$ is the significance of w_k, defined as "the normalized information of the word w_k" in the 5,487,056-word corpus [West, 1953].

3. Observe $a(P(w_k), w_l)$, the activity value of node l in pattern $P(w_k)$ (computed, supposedly, as $v_l(10)$; *see* Equation 2.1). The similarity value sought is then

$$\mathrm{sim}_{\mathrm{KF}}(w_k, w_l) = s(w_l) \cdot a(P(w_k), w_l) \ . \tag{2.2}$$

For instance, to compute the similarity between the words *red* and *orange*, we first induce an activated pattern $P(red)$ on Paradigme. The word significance of *red*, which

[3]The values of both $R_n(T)$ and $R'_n(T)$ depend on the activity values of the members of their respective sets as well as on the thicknesses of the links involved (*see* [Kozima and Furugori, 1993] for details). An interesting point to note is that the final expression for $R_n(T)$ is given in the paper in terms of "the most *plausible* subréférant" of n, which amounts to provisional disambiguation of the word associated with the node (*see* above).

[4]Kozima and Furugori do not provide a precise formula for computing ϕ.

appears 2,308 times in the corpus, is computed as

$$s(red) = \frac{-\log(2308/5487056)}{-\log(1/5487056)} = 0.500955 \ .$$

Since the network contains two nodes with the headword *red*, both of them are activated with the strength $e = 0.500955$. Next, we observe $a(P(red), orange) = 0.390774$ and compute $s(orange) = 0.676253$. According to Equation 2.2 then,

$$\mathrm{sim}_{\mathrm{KF}}(red, orange) = 0.676253 \cdot 0.390774 = 0.264262 \ .$$

The procedure described above defines a similarity measure on elements of the LDV, *i.e.,* $\mathrm{sim}_{\mathrm{KF}} : \mathrm{LDV} \times \mathrm{LDV} \rightarrow [0,1]$,[5] which makes up only about 5% of LDOCE. The natural next step in Kozima and Furugori's research was, therefore, to try and extend the measure to $\mathrm{sim}_{\mathrm{KF}} : \mathrm{LDOCE} \times \mathrm{LDOCE} \rightarrow [0,1]$. This was accomplished indirectly by extending $\mathrm{sim}_{\mathrm{KF}}$ of Equation 2.2 to $\mathrm{sim}_{\mathrm{KF}} : \mathrm{LDV}^n \times \mathrm{LDV}^m \rightarrow [0,1]$, where n and m are essentially arbitrary positive integers: any word in the LDOCE-complement of the LDV was treated as a list $W = \{w_1, \ldots, w_r\}$ of the words in its definition, with the similarity between word lists W, W' defined as

$$\mathrm{sim}_{\mathrm{KF}}(W, W') = \psi\Big(\sum_{w' \in W'} s(w') \cdot a(P(W), w')\Big) \ . \tag{2.3}$$

Here, $P(W)$ is the pattern resulting from the activation of each $w_i \in W$ with strength $s(w_i)^2 / \sum s(w_k)$ for 10 steps,[6] and ψ is a function limiting the output value to $[0,1]$.[7]

An example of applying formula 2.3 is arriving at the similarity value of the words *linguistics* and *stylistics*:

$$\begin{aligned} &\mathrm{sim}_{\mathrm{KF}}(linguistics, stylistics) \\ &\quad = \mathrm{sim}_{\mathrm{KF}}(\{the,\ study,\ of,\ language,\ in,\ general,\ and,\ of,\ particular,\end{aligned}$$

[5] To verify the range, notice that both $s(w)$ and $a(P(w'), w'')$ (Equation 2.2) return values within the interval $[0,1]$.

[6] The significance of a word not found in [West, 1953] was estimated as the average significance of its word class.

[7] Again, no explicit formula is given for ψ in [Kozima and Furugori, 1993].

languages, and, their, structure, and, grammar, and, history},

{*the, study, of, style, in, written, or, spoken, language*})

$= 0.140089$.

2.1.3 Kozima and Ito's Adaptive Scaling of the Semantic Space

Fairly soon after coming up with the technique for computing similarity by means of spreading activation on a dictionary, Kozima and another colleague, Ito [1997], realized that Kozima and Furugori's [1993] method, as well as those of Osgood [1952], Morris and Hirst [1991], and others, can be categorized as *context-free*, or *static*, for it measures the distance between words irrespective of context. They then set out to build on the work of Kozima and Furugori and derive a *context-sensitive*, or *dynamic*, measure by taking into account the "associative direction" for a given word pair.

The motivation behind the newly-proposed method lies in the observations that, when asked to associate words freely from a given word, "we often imagine a certain context for retrieving related words", and, if we change context, the perceived distance for the same word pair will, generally, also change.

In their work, Kozima and Ito represent context by a set C of characteristic words. For example, $C = \{car, bus\}$ imposes the associative direction of vehicle (association sets are then likely to include *taxi, railway, airplane*, etc.), whereas $C = \{car, engine\}$ imposes the direction of components of car (*tire, seat, headlight*, etc.). Denoting the given vocabulary by V, the objective of the method can be expressed as the computation of distance $\mathrm{dist}_{\mathrm{KI}}(w, w'|C)$ between any two words w, w' in V "under the context specified by" C.

The strategy for computing $\mathrm{dist}_{\mathrm{KI}}(w, w'|C)$ is "'adaptive scaling' of a semantic space" in which every word in V is represented as a multidimensional vector. Kozima and Ito adopted LDV as their vocabulary and activated patterns $P(w)$'s (Section 2.1.2) as their vectors (activating the node(s) with w as the headword results in a unique equilibrium

pattern of activity, which admits a trivial vector-representation if we treat the nodes of Paradigme (Section 2.1.2) as coordinates).

By construction, $P(w)$ represents the meaning of w through its relationship with the rest of V. The geometric distance between $P(w)$ and $P(w')$ is then indicative of the semantic distance between w and w' — but it is also *static*. To provide for *context-sensitive* distance, P-vectors are first transformed into Q-vectors by means of principal component analysis. A new set of axes $X = \{X_1, \ldots, X_{2851}\}$ is computed in such a way that it provides an orthonormal coordinate system for P-vectors, and the axes are arranged in descending order of P-vector variance. Then, the first m axes $X_1, \ldots, X_m$ (*see* below) are selected, and every $P(w_i)$ is projected onto each of them. Finally, the projected vectors are 'centered' so that their 'mean vector' is 0.

Since the variance for each axis "indicates the amount of information represented by" that axis, the axes in X are arranged in "descending order of their significance". Plotting the cumulative variance against m shows that even a couple of hundred axes can account for nearly half of the "total information of P-vectors". The exact value of $m = 281$ is obtained by choosing m, $1 \leq m \leq 2851$, resulting in minimal noise (where noise is estimated by $\sum_{w \in F} |Q(w)|$ with F being the set of all function words in V). Thus, principal component analysis both compresses semantic information (by reducing the number of dimensions of the vector space) and reduces the amount of noise present.

Because, as is demonstrated in the paper, semantically related words have close ("similar") P-vectors and since principal component analysis preserves relative distance, in a semantic subspace of Q-vectors with appropriately chosen dimensions words that are related should form clusters. It is the selection of appropriate dimensions (axes) that is accomplished by *adaptive scaling*. The semantic space is altered ("scaled up or down") so as to make the words in $C = \{w_1, \ldots, w_n\}$ close to one another. The distance $\mathrm{dist}_{\mathrm{KI}}(w, w'|C)$ between two words w and w' (with the corresponding $Q(w) = (q_1, \ldots, q_m)$

and $Q(w') = (q'_1, \ldots, q'_m)$) is computed as

$$\mathrm{dist}_{\mathrm{KI}}(w, w'|C) = \sqrt{\sum_{i=1}^{m} (f_i(q_i - q'_i))^2} \ . \tag{2.4}$$

Each $f_i \in [0, 1]$ in the equation is a *scaling factor*, defined as

$$f_i = \begin{cases} 1 - r_i, & r_i \leq 1 \\ 0, & r_i > 1 \end{cases} \ . \tag{2.5}$$

Here,

$$r_i = \mathrm{SD}_i(C)/\mathrm{SD}_i(V) \ , \tag{2.6}$$

where $\mathrm{SD}_i(C)$ is, in turn, the standard deviation of the words in C projected onto X_i and $\mathrm{SD}_i(V)$ is that of the words in V.

If C forms a compact cluster on X_i, the latter becomes a significant axis (*i.e.*, $f_i \approx 1$), and it becomes insignificant ($f_i \approx 0$) if C does not form an "apparent cluster" on X_i. Hence, the process of adaptive scaling "tunes" the distance between Q-vectors to a given word set C, thereby making it context-sensitive. Such a tune-up is not computationally expensive, since the f_i's are the only parameters that change from one context set to another.

2.2 Thesaurus-Based Approaches

2.2.1 Background

Since both approaches described in this section make use of a *Roget's*-type thesaurus, we shall make a couple of remarks about this knowledge source.

Conceived by Peter Mark Roget over 150 years ago, the thesaurus has developed into a massive classification of words and phrases around ideas and concepts. The levels of thesaural hierarchy referred to below include *classes, categories,* and *subcategories.* An essential feature of the thesaurus is its index, which contains category numbers along

with *labels* representative of those categories for each word. Cross-referencing among categories is accomplished with the aid of *pointers*.

As Morris points out, "the thesaurus simply groups words by idea" [Morris, 1988]. In contrast with traditional AI knowledge bases, the thesaurus "does not have to name or classify the idea"; it merely groups related words without attempting to explicitly indicate how and why they are related. Another notable distinction is the following. While, in frame systems or semantic networks, concepts "that are related are actually physically close in the representation ... this need not be true" in a thesaurus. "Physical closeness has some importance ... but words in the index of the thesaurus often have widely scattered categories, and each category often points to a widely scattered selection of categories."

In part as a consequence of the structure of the thesaurus, no numerical value for semantic distance can typically be obtained: rather, algorithms using the thesaurus compute a distance implicitly and return a boolean value of 'close' or 'not close'.

2.2.2 Morris and Hirst's Algorithm

Working with an abridged version of *Roget's Thesaurus*, Morris and Hirst [1991] identified five types of semantic relations between words. In their approach, two words were deemed to be related to one another, or semantically close, if their base forms satisfy any one of the following conditions:

1. they have a category in common in their index entries;
2. one has a category in its index that contains a pointer to a category of the other;
3. one is either a label in the other's index entry or is in a category of the other;
4. they are both contained in the same subcategory;
5. they both have categories in their index entries that point to a common category.

These relations account for such pairings as *wife* and *married*, *car* and *driving*, *blind* and *see*, *reality* and *theoretically*, *brutal* and *terrified*.

Of the five types of relations, perhaps the most intuitively plausible ones — namely, the first two in the list above — were found to validate over 90% of the intuitive lexical relationships that the authors used as a benchmark in their experiments (*see* Section 4.2.2). In addition to the five relations presented so far, two words with identical base forms were, naturally, also considered related. Less trivially, Morris and Hirst came to allow one transitive link with respect to their relation set. That is, if word w_1 is related to word w_2, word w_2 is related to word w_3, and word w_3 is related to word w_4, then w_1 would be considered related to word w_3 but not to word w_4. The introduction of limited transitivity of this kind enabled the authors to relate, for instance, *afraid* to *uneasily* through *trouble*.

Morris and Hirst used their metric for "identifying and tracing patterns of lexical cohesion" (termed *lexical chains*) in free-running text, as will be discussed later in the report.

2.2.3 Okumura and Honda's Algorithm

Morris and Hirst's work on use of thesaurus for analyzing lexical cohesion in English inspired Okumura and Honda's investigation into construction and applications of *lexical chains* for Japanese [Okumura and Honda, 1994].

As far as the determination of word relatedness is concerned, Okumura and Honda's method can be regarded as a restriction of Morris and Hirst's: while they use the Japanese thesaurus *Bunrui-goihyo*, which is similar to *Roget's*, only the first of the five relations listed in the previous subsection is considered sufficient for a pair of words to be related.

We will have more to say about Okumura and Honda's work when we talk about applications in Chapter 4.

2.3 Approaches Using a Semantic Network

2.3.1 Background

According to Lee *et al.* [1993], a "semantic network is broadly described as any representation interlinking nodes with arcs, where the nodes are concepts and the links are various kinds of relationships between concepts."

The majority of the methods discussed in the present and the following section use WordNet [Miller *et al.*, 1990, Fellbaum, 1998], a broad coverage semantic network created as an attempt "to model the lexical knowledge of a native speaker of English" [Richardson and Smeaton, 1995a]. English nouns, verbs, adjectives, and adverbs are organized into synonym sets (*synsets*), each representing one underlying lexical concept, that are interlinked with a variety of relations.

2.3.1.1 Noun Portion of WordNet

The noun portion of WordNet has fairly rich connectivity and remains by far the most developed part of the network. Its more than 60,500 synsets, representing over 107,400 noun senses, are linked by over 150,000 arcs of nine types corresponding to the nine relations adopted by WordNet's creators (*see* below).[8]

The subsumption hierarchy (*hypernymy/hyponymy*) constitutes the backbone of the noun subnetwork, accounting for close to 80% of the links. At the top of the hierarchy are 11 abstract concepts, termed *unique beginners*, such as entity ('something having concrete existence; living or nonliving'), psychological feature ('a feature of the mental life of a living organism'), abstraction ('a concept formed by extracting common features from examples'), shape/form ('the spatial arrangement of something as distinct from its substance'), event ('something that happens at a given place and time'), etc. Hence, strictly speaking, the noun portion consists of eleven separate hierarchies "cover[ing]

[8]The figures given throughout this subsection are for version 1.5 of WordNet (March 1995).

distinct conceptual and lexical domains" [Miller, 1998]. These hierarchies are not entirely disjoint, however, and do not form trees (*i.e.,* multiple inheritance is allowed). The maximum depth of the noun hierarchy is 16 nodes.

The nine types of relations defined on the noun subnetwork are as follows:

hypernymy: the IS-A relation: *e.g.,* plant is a hypernym of tree since tree IS-A plant

hyponymy: the SUBSUMES relation (inverse of **hypernymy**)

meronymy: the set of three relations that can be collectively referred to as PART-OF:

- **component-object:** *e.g.,* branch is a meronym of tree since branch is a component of tree
- **member-collection:** *e.g.,* tree is a meronym of forest since tree is a member of forest
- **stuff-object:** *e.g.,* aluminum is a meronym of airplane since aluminum is the stuff that airplane is made from

holonymy: the set of three relations that can be collectively referred to as HAS-A (and that are the respective inverses of **meronymy**):

- **object-component:** the inverse of the **component-object**
- **collection-member:** the inverse of the **member-collection**
- **object-stuff:** the inverse of the **stuff-object**

antonymy: very roughly, the COMPLEMENT-OF relation (self-inverse): *e.g.,* rise and fall are antonyms, and so are brother and sister.

For the sake of completeness, we also mention the tenth relation, **synonymy**, which is intranode and self-inverse.

2.3.2 Computing Path Length

A natural way to evaluate semantic similarity in a taxonomy, given its graphical representation, is "to evaluate the distance between the nodes corresponding to the items being compared — the shorter the path from one node to another, the more similar they are. Given multiple paths, one takes the length of the shortest one" [Resnik, 1995]. The first approach presented in this section follows exactly this methodology.

2.3.2.1 Rada et al.'s Simple Edge Counting

Rada and colleagues [Rada *et al.*, 1989, Rada and Bicknell, 1989] describe a research effort directed towards improving quality of a bibliographic information retrieval system in a highly specific domain — biomedical literature. Unlike the other approaches below, which use WordNet, Rada *et al.*'s central knowledge source is MeSH (Medical Subject Headings), a hierarchical semantic network[9] of over 15,000 terms used in indexing over five million articles in Medline, one of the world's largest bibliographic retrieval systems, maintained by the National Library of Medicine. The network's 15,000 terms form a nine-level hierarchy that includes high-level nodes such as *anatomy, organism,* and *disease* and is based on the BROADER-THAN relationship. The BROADER-THAN relation is quite similar to (the inverse of) IS-A, but occasionally also includes some other types of links such as (the inverse of) PART-OF. As with IS-A, 'broader' items are placed higher in the tree.

The principal assumption put forward by Rada and colleagues is that "the number of edges between terms in the MeSH hierarchy is a measure of conceptual distance between terms". Their distance $\mathrm{dist}_{\mathrm{Retal}}(t_i, t_j)$ between two terms is thus defined simply as

$$\mathrm{dist}_{\mathrm{Retal}}(t_i, t_j) = \text{minimal number of edges in a path from } t_i \text{ to } t_j \ . \tag{2.7}$$

As we shall see in Section 4.5.1, even with such a simple distance function, the authors

[9] More precisely, MeSH is what in information science is called a faceted thesaurus.

were able to obtain surprisingly good results. In part, their success can be explained by the following general observation of Lee *et al.* [1993]: "In the context of Quillian's semantic networks, shortest path lengths between two concepts are not sufficient to represent conceptual distance between those concepts. *However* [emphasis ours], when the paths are restricted to IS-A links, the shortest path length does measure conceptual distance." Another component of their success is certainly the aforementioned specificity of the domain, which ensures relative homogeneity of the hierarchy.

2.3.2.2 Hirst and St-Onge's Medium-Strong Relations

In an attempt to 'port' Morris and Hirst's lexical chaining algorithm to an on-line lexical knowledge base, Hirst and St-Onge [1998; St-Onge, 1995] distinguished three major types of relations between nouns in WordNet.[10] The **extra-strong** relation holds between a word and its literal repetition. A pair of words is **strong**ly related in one of the following cases:

1. the two words have a synset in common (the pair *human* and *person* is an example of this sort);

2. the two words are associated with two different synsets which are connected by a *horizontal*[11] link (an example here is *precursor* and *successor*);

3. "there is any kind of link at all between a synset associated with each word" but, in addition, one word is a compound (or a phrase) that includes the other (e.g., *school* and *private school*).

[10] The original ideas and definitions (including those for the direction of links — *see* below) contained in [Hirst and St-Onge, 1998] are supposed to apply to all parts of speech and the entire range of relations featured in the WordNet ontology (these include *cause, pertinence, also see*, etc.). Like other researchers, however, they had to resort to the noun subnetwork only. In what follows, therefore, we will use appropriately restricted versions of their notions.

[11] *Antonymy*, from the list in Section 2.3.1.

Finally, they postulated that two words are related in a **medium-strong**, or **regular**, fashion (e.g., *carrot* and *apple*) if there exists an *allowable path* connecting a synset associated with each word. A path is *allowable* if it contains no more than five links and conforms to one of the eight patterns described in [Hirst and St-Onge, 1998]. The justifications of the patterns are grounded in psycholinguistic theories concerning the interplay of generalization, specialization, and coordination; however, both their exact formulation and the concrete shapes of the allowable paths are outside of the scope of this report. All we need to know for the purposes of subsequent discussion is that an allowable path may include more than one link and that the directions of links on the same path may vary (among *horizontal, upward* (*hyponymy* and *meronymy*), and *downward* (*hypernymy* and *holonymy*)).

In Hirst and St-Onge's framework, **extra-strong** relations have precedence over **strong** relations, and **strong** relations outweigh **medium-strong** ones. Also, by definition, there is no 'competition' within the first two categories. This, however, is not true of **medium-strong** relations — and this explains why the method is presented in this section. Each path is assigned a weight given by the following formula:

$$\text{weight} = C - \text{path length} - k \times \text{number of changes of direction} , \tag{2.8}$$

where C and k are constants. The intuition behind the formula is that "the longer the path and the more changes of direction, the lower the weight". Evidently, Equation 2.8 induces a partial[12] distance function on the space of WordNet noun entries, which can be made total (and computable in the sense of Church), for instance, by assigning all **extra-strong** relations the value of $3C$, **strong** relations the value of $2C$, **medium-strong** relations the weight of the corresponding path, and **weak** relations the value of 0.

[12] Again, because of the task at hand, Hirst and St-Onge did not require that any two nodes be commensurate. More precisely, a relation not falling into any of the three categories given above was declared **weak** and eliminated from further consideration.

2.3.3 Scaling the Network

Despite its apparent simplicity, a widely acknowledged problem with the edge counting approach is that it typically "relies on the notion that links in the taxonomy represent uniform distances", which is typically not true: "there is a wide variability in the 'distance' covered by a single taxonomic link, particularly when certain sub-taxonomies (*e.g.*, biological categories) are much denser than others" [Resnik, 1995]. Resnik uses rabbit ears IS-A television antenna as an example of a link that covers an intuitively narrow distance and phytoplankton IS-A living thing as an example of one covering intuitively wide distance.[13] The approaches discussed below demonstrate attempts undertaken by various researchers to overcome this problem.

2.3.3.1 Sussna's Depth-Relative Scaling

In Sussna's [1993, 1997] approach, each edge in the WordNet noun network is construed as consisting of two arcs representing inverse relations (*see* Section 2.3.1). Each relation r has a weight or a range $[\min_r; \max_r]$ of weights associated with it: all *antonymy* arcs get the value of $\min_r = \max_r = 2.5$, *hypernymy, hyponymy, holonymy,* and *meronymy* have weights between $\min_r = 1$ and $\max_r = 2$.[14] (Since *synonymy* is an intranode relation, its (non-existent) arcs get weight 0.) The point in the range for a relation r arc from node c_1 to node c_2 depends on the number n_r of arcs of the same type leaving c_1; namely,

$$w(c_1 \rightarrow_r c_2) = \max_r - \frac{\max_r - \min_r}{n_r(c_1)} \; . \tag{2.9}$$

This is the *type*[15]*-specific fanout* factor, which, according to Sussna, "reflects dilution of the *strength of connotation* between a source and target node" and "takes into account

[13] Both examples are from Resnik [1995], who presumably used an earlier version of WordNet. According to WordNet1.5, phytoplankton IS-A plant IS-A living thing; however, we believe that his point still remains valid: consider, for example, white elephant IS-A possession, home ('the country or state or city where you live') IS-A location ('a point or extent in space'), or earth ('the abode of mortals (as contrasted with heaven or hell)') IS-A location ('a point or extent in space').

[14] Experiments proved the precise details of the weighting scheme to be material only in fine-tuning the performance.

[15] Here *type* refers to the type of the relation, i.e., r.

the possible asymmetry between the two nodes, where the strength of connotation in one direction differs from that in the other direction". The two inverse weights for an edge are averaged and scaled by depth d of the edge "within the overall 'tree'" (*see* Section 5.4.1.2). The key motivation for scaling is Sussna's observation that sibling-concepts deeper in the tree appear to be more closely related to one another than those higher in the tree. The formula for the distance between adjacent nodes c_1 and c_2 then becomes

$$\text{dist}_S(c_1, c_2) = \frac{w(c_1 \rightarrow_r c_2) + w(c_2 \rightarrow_{r'} c_1)}{2d} , \tag{2.10}$$

where r is the relation that holds between c_1 and c_2 and r' is its inverse (*i.e.,* the relation that holds between c_2 and c_1).

Finally, the semantic distance between two arbitrary nodes c_i and c_j is computed as the sum of the distances between the pairs of adjacent nodes along the shortest path connecting c_i and c_j.

2.3.3.2 Wu and Palmer's Conceptual Similarity

In a paper focusing on "semantic representation of verbs in computer systems and its impact on lexical selection problems in machine translation", Wu and Palmer [1994] devote a couple of paragraphs to introducing a metric that is somewhat specialized but nonetheless deserving of at least a brief mention. Very superficially, the key idea of the authors' approach to translating English verbs into Mandarin Chinese is to "project" verbs (and verb compounds) of both languages onto something they call "conceptual domains"[16]. The first immediate effect of the projection operation is that it separates different senses of verbs by placing them into different domains. Another important feature of conceptual domains — and the one that directly concerns us — is the fact that the concepts within a single domain can be organized in a strict hierarchical structure

[16] Unfortunately, the authors do not seem to provide any insights regarding the notion aside from mentioning that they relied on "the semantic domains suggested by Levin".

(namely, a tree)[17] on which a measure of similarity can be defined.

Wu and Palmer define *Conceptual Similarity* between a pair of concepts c_1 and c_2 as

$$\mathrm{sim}_{\mathrm{WP}}(c_1, c_2) = \frac{2 \times N3}{N1 + N2 + 2 \times N3} , \tag{2.11}$$

where $N1$ is the length (in number of nodes) of the path from c_1 to c_3, which is the least common superconcept of c_1 and c_2, $N2$ is the length of the path from c_2 to c_3, and $N3$ is the length of the path from c_3 to the root of the hierarchy. Note that $N3$ represents the 'global' depth in the hierarchy, and to emphasize its role as a scaling factor more clearly, we can consider a translation of Equation 2.11 from the language of similarity into the language of *distance*:

$$\mathrm{dist}_{\mathrm{WP}}(c_1, c_2) = 1 - \mathrm{sim}_{\mathrm{WP}}(c_1, c_2) = \frac{N1 + N2}{N1 + N2 + 2 \times N3} . \tag{2.12}$$

2.3.3.3 Leacock and Chodorow's Normalized Path Length

In the course of their attempt to alleviate the problem of sparseness of training data for a statistical local-context classifier (*see* Section 4.1.3), Leacock and Chodorow [1998] proposed the following formula for computing the semantic similarity between words w_1 and w_2 (notation borrowed from [Resnik, 1995]):

$$\mathrm{sim}_{\mathrm{LC}}(w_1, w_2) = -\log \frac{\min_{c_1, c_2} \mathrm{len}(c_1, c_2)}{2 \times D} , \tag{2.13}$$

where D is the maximum depth of the taxonomy (also known as *height*, in graph theory), $\mathrm{len}(c_1, c_2)$ is the length of the shortest path between c_1 and c_2, and c_i ranges over $s(w_i)$ $(i = 1, 2)$, which, in turn, stands for "the set of concepts in the taxonomy that are senses of word w_i" [Resnik, 1995].

[17] After completing the projection of verbs in both languages, all the corresponding conceptual domains are merged to form "interlingua conceptual domains". One of the reasons it is possible to organize such domains in nice hierarchies is that some of their nodes are 'pure' concepts as opposed to 'lexicalized' concepts. For example, in the "Change-of-State" domain, given in the paper as an illustration, neither the root, Change-of-State, nor two of its children, Cause-feeling and Concrete-object-change-of-state, have words of English or Chinese attached to them.

To avoid singularities, Leacock and Chodorow measure path lengths in nodes, rather than edges, so synonyms (*i.e.,* members of the same synset) are 1 unit of distance apart from each other. Like many other researchers, the authors also posit a global root above the 11 unique beginners (Section 2.3.1) to ensure the existence of a path between any two nodes.

2.3.3.4 Agirre and Rigau's Conceptual Density

Agirre and Rigau [1996, 1997] set out to derive a measure of conceptual distance sensitive to the following parameters:

- the length of the shortest path that connects the concepts involved;
- the depth in the hierarchy: concepts in a deeper part of the hierarchy should be ranked closer;
- the density of concepts in the hierarchy: concepts in a dense part of the hierarchy are relatively closer than those in a more sparse region;

However, despite their stated goals, an explicit formula for such a measure of *distance* (or even a reference to one) does not appear in either [Agirre and Rigau, 1997] or [Agirre and Rigau, 1996]. Instead, Agirre and Rigau introduce and develop the notion of conceptual *density* (*see* below). As we shall see in Section 4.1.1, however, the latter could be used as a stepping stone to determining semantic relatedness between, in effect, an arbitrary number of words — and this is why it is included in our discussion.

The result of Agirre and Rigau's endeavor is the following definition. Given a sub-hierarchy, with a concept c as its topmost node (root), that contains, among others, m concepts of interest, the Conceptual Density of c with respect to the m concepts is defined as

$$\mathrm{CD}(c,m) = \frac{\sum_{i=0}^{m-1}(nhyp_c)^i}{\sum_{i=0}^{h-1}(nhyp_c)^i} \ , \tag{2.14}$$

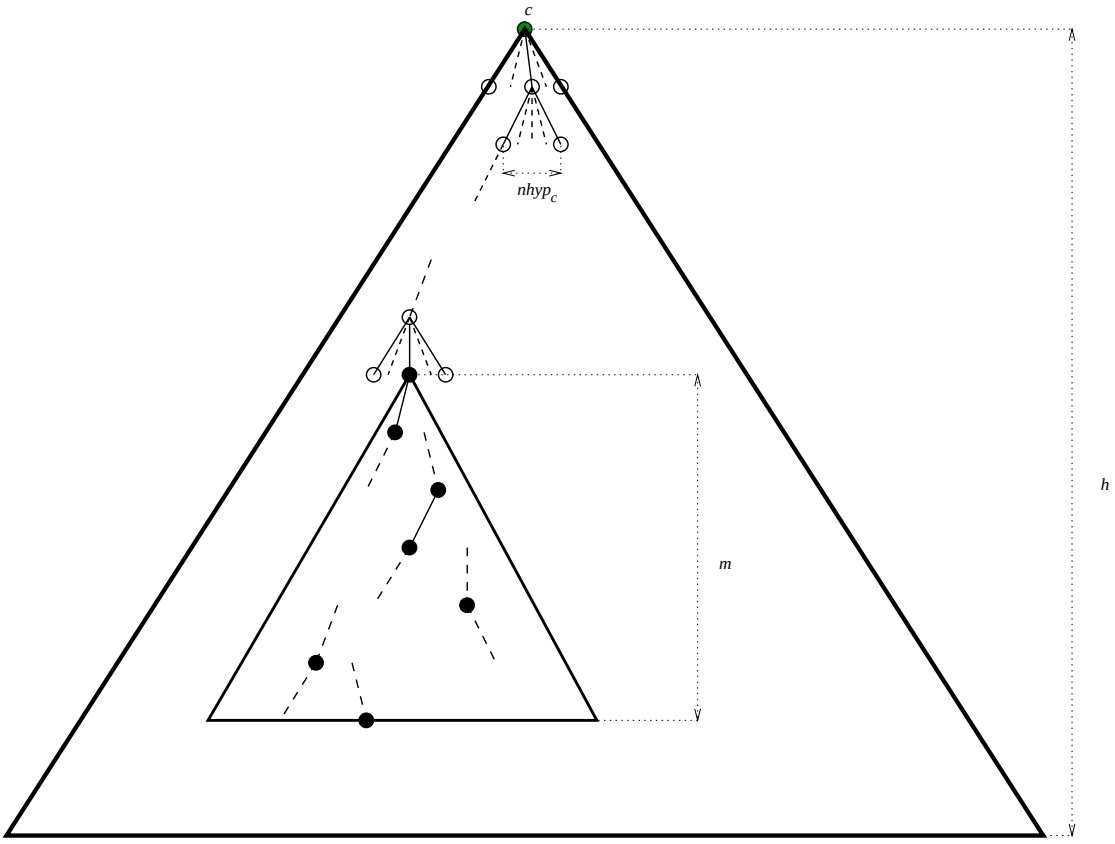

Figure 2.1: The quasi-geometric intuition behind Formula 2.14 for the case $m < h$. The outer triangle marks the boundary of the subhierarchy rooted in c; the inner that of the expected subhierarchy containing the m concepts of interest (depicted as solid-filled circles).

where $nhyp_c$ is the mean number of hyponyms per node in c's subhierarchy (*see* below) and h is the height of the subhierarchy.[18]

This formula can be given a quasi-geometric interpretation, as follows. If our subhierarchy were a *perfect* $nhyp_c$-ary tree and the 'area' of a hierarchy were taken to be the number of concepts in it, then (*see* Figure 2.1) the denominator of the right-hand side of Equation 2.14 would represent precisely the area of the subhierarchy rooted in c. Similarly, the numerator would then represent the area of the largest minimal hierarchy

[18]Like Leacock and Chodorow (Section 2.3.3.3), Agirre and Rigau measure heights in nodes, so a hierarchy consisting of a single concept (e.g., c alone) is considered to have height $h = 1$.

required to accommodate m concepts (*i.e.,* the (expected) case of each of the m concepts occurring at a different, but adjacent, (depth) level, thus resulting in a hierarchy of height m). The fraction on the right-hand side of 2.14 would then express the ratio between the areas of the expected-case hierarchy 'covering' m concepts of interest and the actual hierarchy in which they are found, hence justifying the term *density* in the name of the measure. (Note, that if $m > h$, then also $CD(c, m) > 1$.)

In fact, our premise concerning a perfect $nhyp_c$-ary tree is not as unrealistic as it may appear at first: the value of $nhyp_c$, in Agirre and Rigau's method, is computed for each concept c in WordNet from the following equation:

$$\text{descendants}_c = \sum_{i=0}^{h-1} nhyp_c^i \ . \tag{2.15}$$

Here, descendants_c is the number of concepts in the subhierarchy below c, including c itself;[19] thus the denominator of the right-hand side of Equation 2.14 does indeed express the total number of concepts in c's subhierarchy.

Once the basic formula (Equation 2.14) had been established, the authors decided to investigate possibilities of fine-tuning it by introducing parameters α and β as follows:

$$\text{CD}(c, m) = \frac{\sum_{i=0}^{m-1} (nhyp_c + \beta)^{i^\alpha}}{\text{descendants}_c} \ . \tag{2.16}$$

After extensive experimentation with different values of α and β, the authors concluded that the latter does not affect the behavior of the formula, while the former does, yielding the best results with α in the vicinity of 0.2. The final formula for Conceptual Density is thus:

$$\text{CD}(c, m) = \frac{\sum_{i=0}^{m-1} nhyp_c^{i^{0.2}}}{\text{descendants}_c} \ . \tag{2.17}$$

[19] Agirre and Rigau are rather vague about the meaning of descendants_c, never explicitly defining it. They do, however, describe Equation 2.15 as capturing "the relation among height, averaged number of hyponyms of each sense, and total number of senses in a subhierarchy" [Agirre and Rigau, 1997] and mention "the number of descendant senses of concept c" (ibid.) when talking about the denominator of the fraction in 2.14. Both of these remarks seem to corroborate our reading of the notation.

2.4 Integrated Approaches

Like the methods in the preceding subsection, the final group of approaches that we present in this report attempt to counter problems inherent in a general ontology. These approaches incorporate an additional, and qualitatively different, knowledge source: all three techniques outlined below use corpus analysis to augment the information already present in the network. As a side-effect, this "provides a way of adapting a static knowledge structure to multiple contexts" [Resnik, 1995].

2.4.1 Resnik's Information-Based Approach

The key underlying idea of Resnik's [1995] approach is the intuition that one criterion of similarity between two concepts is "the extent to which they share information in common", which in an IS-A taxonomy can be determined by inspecting the relative position of a most specific concept that subsumes them both.[20] This intuition seems to be indirectly captured by edge-counting methods (such as that of Rada and colleagues Section 2.3.2.1) in that "if the minimal path of IS-A links between two nodes is long, that means it is necessary to go high in the taxonomy, to more abstract concepts, in order to find a least upper bound". An example given in [Resnik, 1995] is the difference in the relative positions of the most specific subsumer of nickel and dime — coin — and that of nickel and credit card — medium of exchange (*see* Figure 2.2).

In mathematical terms, let us augment our taxonomy (whose set of concepts is denoted by $\mathcal{C}$) with a function $p : \mathcal{C} \rightarrow [0, 1]$, such that for any $c \in \mathcal{C}$, $p(c)$ is the probability of encountering an *instance* of concept c. Following the standard definition from Information Theory, the *information content* of c is then $-\log p(c)$. Finally, for a pair of concepts c_1 and c_2, we can define their semantic similarity as

$$\mathrm{sim}_{\mathrm{R}}(c_1, c_2) = \max_{c \in S(c_1, c_2)} [-\log p(c)] = -\log p(lso(c_1, c_2)) \,, \tag{2.18}$$

[20] Resnik allows multiple inheritance in a taxonomy.

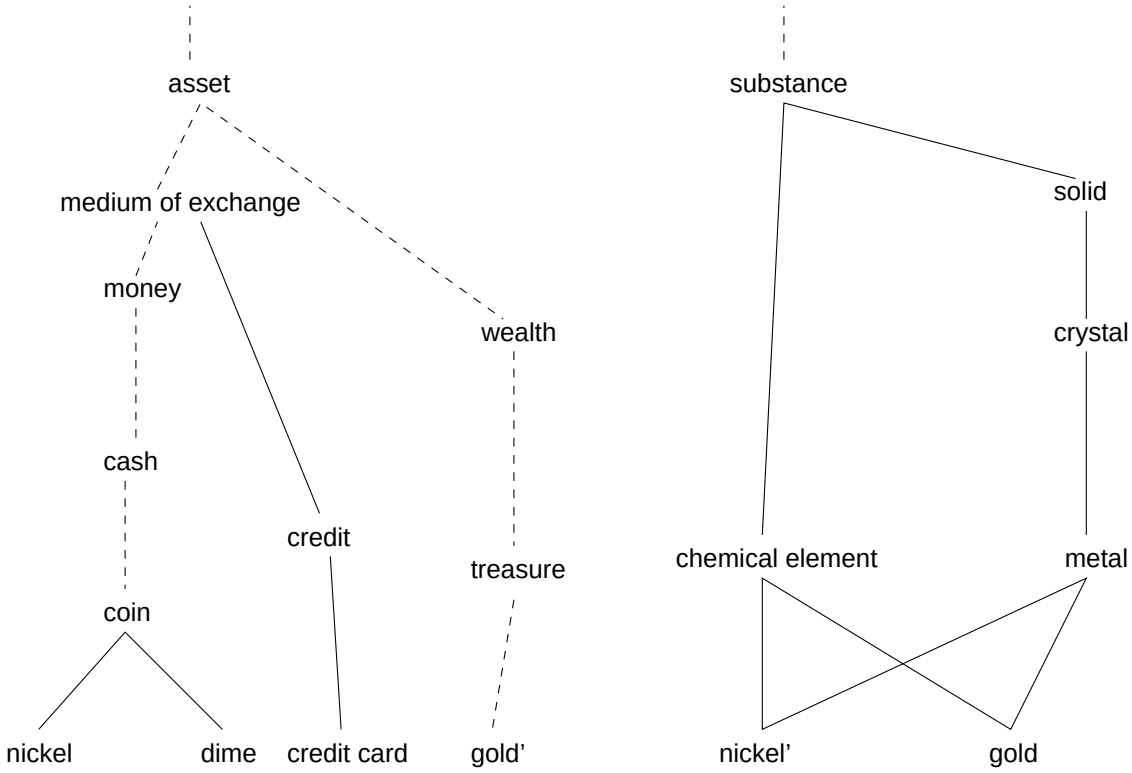

Figure 2.2: Fragment of the WordNet taxonomy. Solid lines represent IS-A links; dashed lines indicate that some intervening nodes have been omitted. Adapted from [Resnik, 1995].

where $S(c_1, c_2)$ stands for the set of concepts that subsume both c_1 and c_2, and $lso(c_1, c_2)$ stands for the most specific common subsumer (*lowest super-ordinate*) of c_1 and c_2.

One thing to note about our definition of p is that it is monotonic as one moves up the taxonomy: c_1 IS-A c_2 implies $p(c_1) \leq p(c_2)$.[21] In particular, if the taxonomy has a unique top node (such as *um-thing* in PENMAN Upper Model), its p is 1. As a consequence, the higher the position of the most specific subsumer for given two concepts in the taxonomy (*i.e.,* the more abstract it is), the lower the similarity. In particular, if the most specific subsumer of a pair of concepts is the top node, their similarity is 0.

Given our formula for similarity between two concepts, the similarity between two

[21] Whenever we encounter a nickel, we have encountered a coin (Figure 2.2), so $p(\text{nickel}) \leq p(\text{coin})$.

words w_1 and w_2 can be calculated as

$$\mathrm{sim}_{\mathrm{R}}(w_1, w_2) = \max_{c_1 \in s(w_1), c_2 \in s(w_2)} [\mathrm{sim}(c_1, c_2)] \,, \tag{2.19}$$

with $s(w_i)$ $(i = 1, 2)$ as in Equation 2.13 (Section 2.3.3.3).

In Resnik's experiments, frequencies of concepts in the taxonomy were estimated through noun frequencies gathered from the Brown Corpus of American English [Francis and Kučera, 1982], a 1-million-word "collection of text across genres ranging from news articles to science fiction". The key characteristic of his counting method is that an individual occurrence of any noun in the corpus "was counted as an occurrence of each taxonomic class containing it" (*see* below). For example, an occurrence of the noun *nickel* was, in accordance with Figure 2.2, counted towards the frequency of nickel, coin, and so forth. Note that, as a consequence of using raw (non-disambiguated) data, encountering a word will contribute to the counts of all its senses (if it is polysemous) and those of any of its homographs. So in case of *nickel*, the counts of nickel′, chemical element, metal, etc., will also be increased.

Formally,

$$\mathrm{freq}(c) = \sum_{n \in \mathrm{words}(c)} \mathrm{count}(n) \,, \tag{2.20}$$

where words(c) is the set of words whose senses are subsumed by concept c (provided that subsumption is reflexive), and, adopting the maximum likelihood estimate (MLE) rule,

$$p(c) = \frac{\mathrm{freq}(c)}{N} \,, \tag{2.21}$$

where N is the total number of nouns in the corpus which are also present in WordNet.

2.4.2 Jiang and Conrath's Combined Approach

Resnik's approach described above attempts to deal with the problem of "varying link distances" [Resnik, 1995] (*see* Section 2.3.3) by generally downplaying the role of network

edges in the determination of the degree of semantic proximity: edges are used solely for locating super-ordinates of a pair of concepts; in particular, the number of links does not figure in any of the formulas pertaining to the method; numerical evidence comes from corpus statistics, which are associated with nodes.

Such a selective use of the structure of the taxonomy, however, has its drawbacks, one of which is the indistinguishability, in terms of semantic distance, of any two pairs of concepts having the same most-specific subsumer. Going back to Figure 2.2, $\mathrm{sim_R}(\mathsf{money}, \mathsf{credit}) = \mathrm{sim_R}(\mathsf{dime}, \mathsf{credit\ card}) = -\log p(\mathsf{medium\ of\ exchange})$, whereas, for a typical *edge-based* method such as Leacock and Chodorow's (Section 2.3.3.3), clearly $\mathrm{sim_{LC}}(\mathsf{money}, \mathsf{credit}) \neq \mathrm{sim_{LC}}(\mathsf{dime}, \mathsf{credit\ card})$.

Jiang and Conrath's [1997] idea was to synthesize edge- and node-based techniques (hence it is a *combined* approach) by effectively restoring the dominant function of network edges in similarity computations and using corpus statistics as a corrective factor. They hypothesized that the general formula for the weight of a link between a child-concept c_c and its parent-concept c_p in a hierarchy should be of the form

$$wt(c_c, c_p) = \left(\beta + (1-\beta)\frac{\bar{E}}{E(c_p)}\right)\left(\frac{d(c_p)+1}{d(c_p)}\right)^{\alpha} LS(c_c, c_p)\, T(c_c, c_p)\ , \tag{2.22}$$

where $E(c_p)$ denotes the number of children of c_p ("local density"), $\bar{E}$ denotes the average local density over the entire hierarchy, $d(c_p)$ the depth of the node c_p in the hierarchy, $LS(c_c, c_p)$ the strength of the link between c_c and c_p, $T(c_c, c_p)$ the link-type coefficient, and the parameters $\alpha \in [0, \infty)$ and $\beta \in [0, 1]$ control the degree of contribution of the node depth and the density factor, respectively. A careful reader may notice a parallel between the local density, node depth, and link-type factors in Equation 2.22 and type-specific fanout, edge depth, and relation weight of Sussna's approach (Section 2.3.3.1). The emphases of the two research programs, however, have been different. Unlike Sussna, Jiang and Conrath to date have experimented only with a single link-type, IS-A (personal communication), which was assigned T of 1. Their investigation into the roles of the density and depth components have demonstrated that "they are not the major

determinants of the overall edge weight": setting $\alpha = 0.5$ and $\beta = 0.3$ resulted in "a small performance improvement" over the simplest case of $\alpha = 0$ and $\beta = 1$ (*i.e.*, giving no consideration to density or depth). The main focus of Jiang and Conrath's effort has thus been the link-strength factor, with Equation 2.22 reduced to the special case

$$wt(c_c, c_p) = LS(c_c, c_p) \; . \tag{2.23}$$

In the framework of the IS-A hierarchy, Jiang and Conrath postulated the strength $LS(c_c, c_p)$ of the link connecting a child-concept c_c to its parent-concept c_p to be proportionate to the conditional probability $p(c_c|c_p)$ of encountering an instance of c_c given an instance of c_p. More specifically,

$$LS(c_c, c_p) = -\log p(c_c|c_p) \; . \tag{2.24}$$

By definition,

$$p(c_c|c_p) = \frac{p(c_c \& c_p)}{p(c_p)} \; . \tag{2.25}$$

If we adopt Resnik's scheme for assigning probabilities to concepts (Section 2.4.1), then $p(c_c \& c_p) = p(c_c)$, since any instance of a child is automatically an instance of its parent (*see* footnote 21). Then,

$$p(c_c|c_p) = \frac{p(c_c)}{p(c_p)} \; , \tag{2.26}$$

and

$$LS(c_c, c_p) = IC(c_c) - IC(c_p) \tag{2.27}$$

if we let $IC(c)$ stand for the information content of concept c.

As per common practice, the semantic distance between an arbitrary pair of nodes was taken to be the sum of the weights of the edges along the shortest path that connects the nodes:

$$\mathrm{dist}_{\mathrm{JC}}(c_1, c_2) = \sum_{c \in \mathrm{path}(c_1, c_2) \setminus lso(c_1, c_2)} wt(c, par(c)) \; . \tag{2.28}$$

Here, $\mathrm{path}(c_1, c_2)$ is the set of all the nodes in the shortest path from c_1 to c_2, and $par(c)$ returns the parent of the node c. One of the elements of $\mathrm{path}(c_1, c_2)$ in an IS-A hierarchy

will always be the most specific common subsumer of the two concepts, $lso(c_1, c_2)$ (*see* Section 2.4.1). Furthermore (and this explains its removal from path(c_1, c_2) in (2.28)), it will be the only element without a parent in the same set.

Expanding the sum in the right-hand side of Equation 2.28, plugging in the expression for the edge weight from Equation 2.23, and performing necessary eliminations will result in the following final formulas for the semantic distance between concepts c_1 and c_2:

$$\text{dist}_{\text{JC}}(c_1, c_2) = IC(c_1) + IC(c_2) - 2 \times IC(lso(c_1, c_2)) \ , \tag{2.29}$$

or

$$\text{dist}_{\text{JC}}(c_1, c_2) = 2 \log p(lso(c_1, c_2)) - (\log p(c_1) + \log p(c_2)) \ . \tag{2.30}$$

2.4.3 Lin's Universal Similarity Measure

Having noticed that all of the similarity measures known to him are tied to a particular application, domain, or resource, Lin [1997a, 1997b, 1998] undertook an attempt to define a measure of similarity that is both universal (applicable to arbitrary objects and "not presuming any form of knowledge representation") and theoretically justified ("derived from a set of assumptions" — instead of "directly by a formula" — so that "if the assumptions are deemed reasonable, the similarity measure necessarily follows"). In arriving at such a definition, he used the following three intuitions as a basis:

1. The similarity between A and B is related to their commonality.[22] The more commonality they share, the more similar they are.

2. The similarity between A and B is related to the differences between them. The more differences they have, the less similar they are.

3. The maximum similarity between A and B is reached when A and B are identical, no matter how much commonality they share.

[22] Throughout this subsection, A and B will denote *arbitrary objects*.

Lin also found it necessary to introduce a few additional assumptions (and definitions), notably that the *commonality* between A and B is measured by the amount of information contained in "the proposition that states the commonalities" between them, formally

$$IC(\text{common}(A, B)) \,, \tag{2.31}$$

and that the *difference* between A and B is measured by

$$IC(\text{description}(A, B)) - IC(\text{common}(A, B)) \,, \tag{2.32}$$

where description(A, B) is a proposition describing what A and B are.

Given the above setting and the apparatus of Information Theory, Lin was able to prove the following

> **Similarity Theorem:** The similarity between A and B is measured by the ratio between the amount of information needed to state their commonality and the information needed to fully describe what they are:
>
> $$\text{sim}_{\text{L}}(A, B) = \frac{\log P(\text{common}(A, B))}{\log P(\text{description}(A, B))} \,. \tag{2.33}$$

His measure of similarity between two concepts in a taxonomy ensued as a corollary:

$$\text{sim}_{\text{L}}(c_1, c_2) = \frac{2 \times \log p(lso(c_1, c_2))}{\log p(c_1) + \log p(c_2)} \,, \tag{2.34}$$

where the notation is consistent with Equations 2.18 and 2.30. (The probabilities $p(c)$ are determined in a manner analogous to Resnik's $p_B(c)$ (Equation 2.21); refer to [Lin, 1997a] for details.)

As Lin points out, Resnik's similarity measure (Equation 2.18) is "quite close" to sim_{L}. In fact, it can be shown that $\text{sim}_{\text{R}}(c_1, c_2) = \frac{1}{2} IC(\text{common}(c_1, c_2))$. What may be a little more unexpected, Lin demonstrates that, under certain conditions, his similarity measure coincides with Wu and Palmer's $\text{sim}_{\text{WP}}(c_1, c_2)$ (Equation 2.11).

Chapter 3

Comparison with Human Judgement

3.1 Assessing Measures of Semantic Relatedness

How can we reason about computational measures of semantic relatedness? Given a single measure, can we tell whether it is a good or a poor one? Given two measures, can we tell whether one is better than the other?

Evaluation of semantic relatedness measures remains an open question [Agirre and Rigau, 1997, Resnik, 1995, Hirst and St-Onge, 1998]. In our survey of literature on the topic, we have come across three prevalent approaches: mathematical analysis, comparison with human judgement, and application-specific evaluation.

The first approach (see, *e.g.,* [Wei, 1993, Lin, 1998]) consists in a (chiefly) theoretical examination of mathematical properties of a measure, such as whether it is actually a metric, whether it has singularities, whether its parameter-projections are smooth functions, etc. Such analyses, in our opinion, may certainly aid the comparison of several measures but perhaps not so much their individual assessment.

The second approach, comparison with human judgements of relatedness, does not appear to suffer from the same limitations; in fact, it arguably yields the most generic assessment of the 'goodness' of a measure; however, its major drawback lies in the difficulty

of obtaining such judgements (*i.e.,* designing a psycholinguistic experiment, validating its results, etc.). In his [1995] paper, Resnik presented a comparison of the ratings produced by his measure sim_{R} (and a couple of others) with those produced by human subjects on a set of 30 word pairs (actually 28; *see* footnote 4, page 35) from an experiment by Miller and Charles [1991]. The fact that others [Jiang and Conrath, 1997, Lin, 1998] followed his lead and employed the same modestly sized dataset in their work appears to be a testament to the seriousness of the problem.

Because of these deficiencies, we, generally, have to take sides with the remaining group of researchers who have chosen to evaluate their measures in the framework of a particular NLP application (*see* Chapter 5).

However, since the trend *has* been established and since we have also found a use for the results in our application-specific evaluation (Chapter 5), we decided to have the measures implemented as part of the application-specific evaluation[1] rate the Miller–Charles pairs, as well as a superset thereof, and compare the ratings obtained with those of human judges. The remainder of this chapter, then, discusses the outcome of our effort.

3.2 The Data

The Miller–Charles word pairs mentioned above were actually derived from an earlier study [Rubenstein and Goodenough, 1965]. As a part of an investigation into "the relationship between similarity of context and similarity of meaning (synonymy)", Rubenstein and Goodenough obtained "synonymy judgements" by 51 human subjects on 65 pairs of words. The pairs ranged from "highly synonymous" to "semantically unrelated", and the subjects were asked to rate them, on the scale of 0.0 to 4.0, according to their "similarity of meaning" (*see* Table 3.1, columns 2 and 3). For the purposes of their study

[1] *See* Section 5.4.1 for the selection rationale and the implementation specifics.

(in effect, rather similar in nature to Rubenstein and Goodenough's), Miller and Charles extracted 30 pairs from the original 65, taking 10 from the "high level (between 3 and 4...), 10 from the intermediate level (between 1 and 3), and 10 from the low level (0 to 1) of semantic similarity", and then obtained similarity judgements from 38 subjects, given the same instructions as above, on those 30 pairs (*see* Table 3.2, columns 2 and 3).[2]

3.3 The Results

The mean ratings from Rubenstein and Goodenough's [1965] and Miller and Charles's [1991] original experiments (labeled 'Humans') and the ratings of the Rubenstein–Goodenough and Miller–Charles word pairs produced by (our implementations of) the Hirst–St-Onge, Jiang–Conrath, Leacock–Chodorow, Lin, and Resnik measures of relatedness are given in Tables 3.1 and 3.2, and their graphical images in Figures 3.1 and 3.2.[3]

3.3.1 Discussion

Since what we are interested in overall when comparing two sets of ratings is the strength of the linear association between two quantitative variables, we follow Resnik [1995] in summarizing the comparison results by means of the coefficient of correlation with the reported human ratings for each computational measure (Table 3.3).[4]

[2] As a result of a typographical error that occurred in the course of either Miller and Charles's actual experiments or the publication thereof, the Rubenstein–Goodenough pair *cord–smile* became transformed into *chord–smile*. Probably because of the comparable degree of (dis)similarity, the error was not discovered and the latter pair has been used in all subsequent work.

[3] We have kept the original orderings of the pairs: from dissimilar to similar for the Rubenstein–Goodenough data and from similar to dissimilar for Miller–Charles. This explains why the two groups of graphs (Figures 3.1 and 3.2) as wholes have the opposite directions. Notice that because $\mathrm{dist}_{\mathrm{JC}}$ measures *distance*, the Jiang–Conrath plot stands out within each group.

[4] Resnik [1995], Jiang and Conrath [1997], and Lin [1998] report the coefficients of correlation between their measures and the Miller–Charles ratings to be 0.7911, 0.8282, and 0.8339, respectively, which slightly differ from the corresponding figures in Table 3.3. These discrepancies can be explained by possible minor differences in implementation (*e.g.,* the compound recognition mechanism used in collecting the frequency data), differences between the versions of WordNet used in experiments (Resnik),

Table 3.1: Human and computer ratings of the Rubenstein–Goodenough dataset.

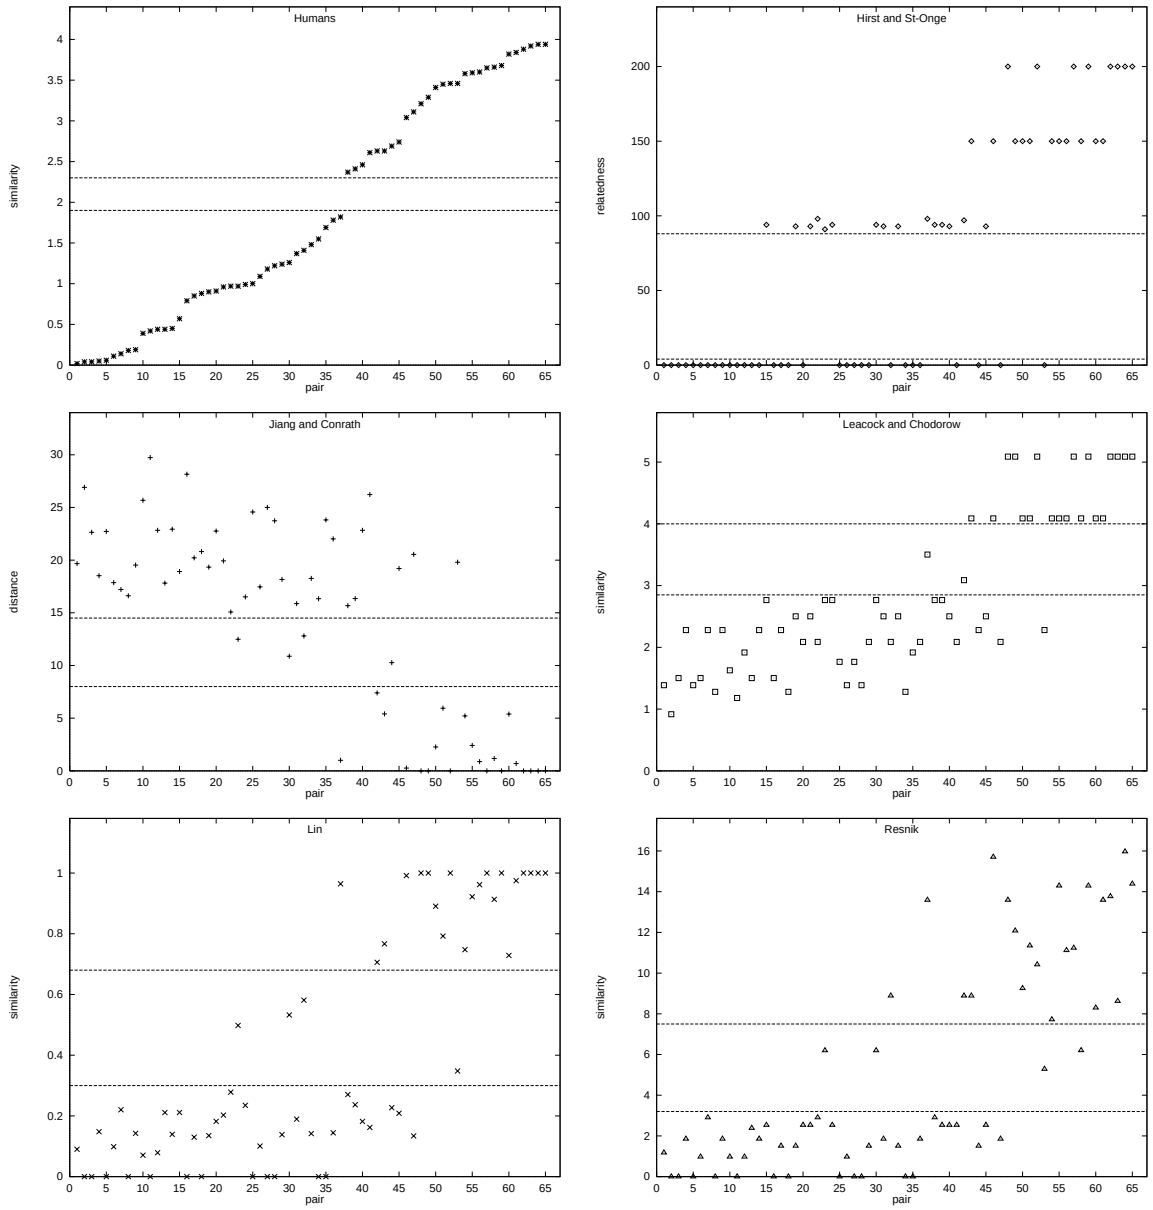

Figure 3.1: Human and computer ratings of the Rubenstein–Goodenough dataset.

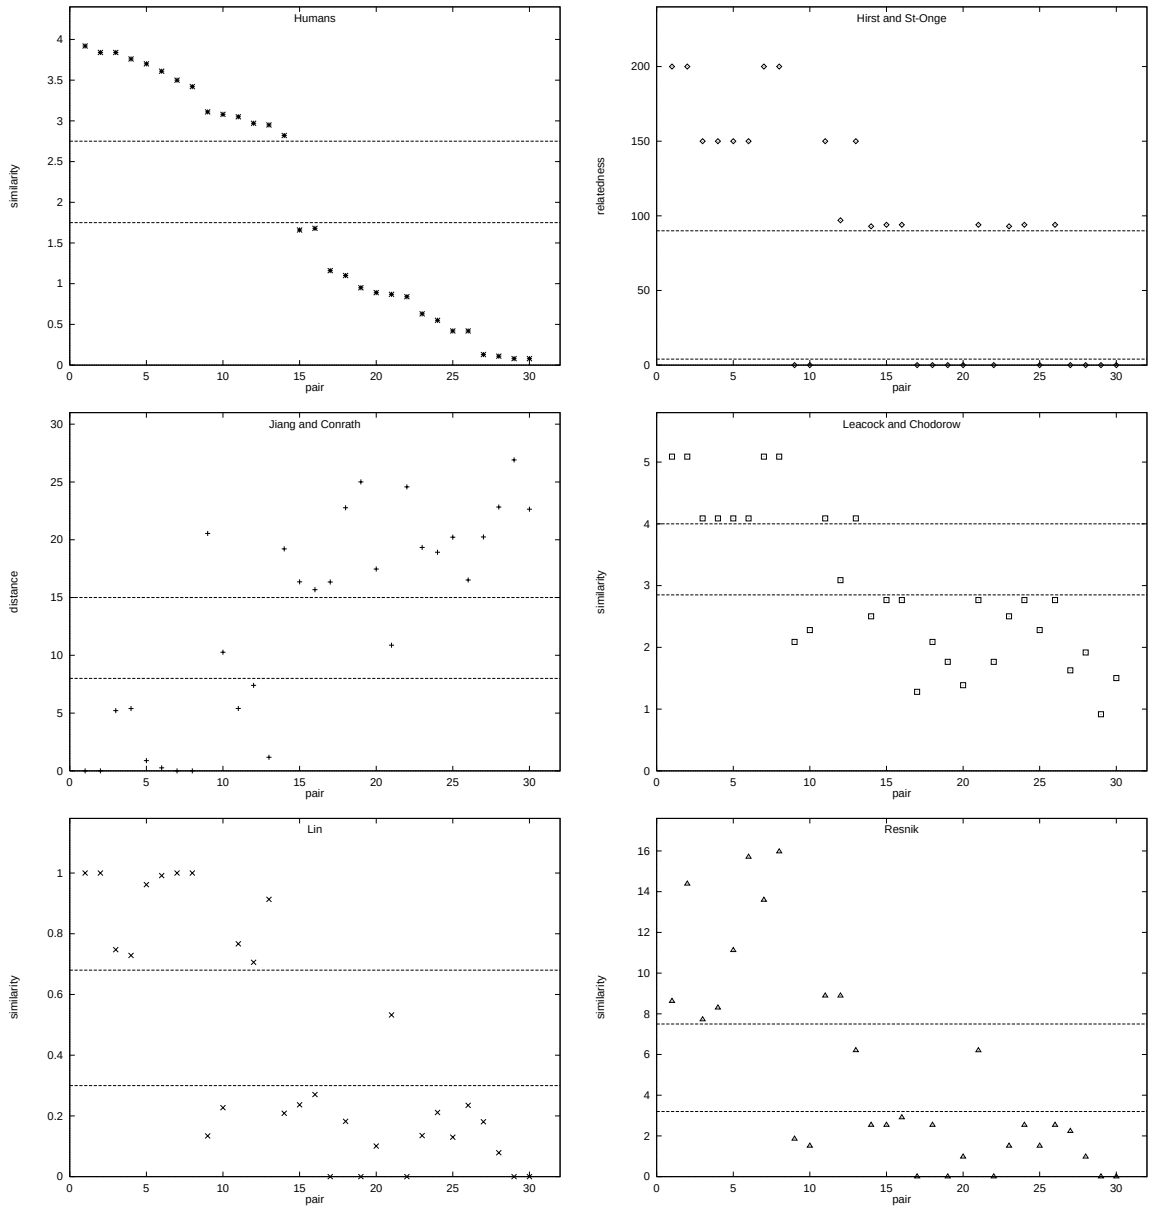

Figure 3.2: Human and computer ratings of the Miller–Charles dataset.

Table 3.3: The coefficients of correlation between the computer and human ratings.[5]

Measure	Miller–Charles	Rubenstein–Goodenough
Hirst and St-Onge	0.7443990930	0.7861440344
Jiang and Conrath	0.8500267204	0.7812746298
Leacock and Chodorow	0.8157413049	0.8382296528
Lin	0.8291711020	0.8193023545
Resnik	0.7736382148	0.7786845861

To get an idea of the upper bound on performance of a computational measure, we could, again, refer to human performance. Since Rubenstein and Goodenough's experiment has not, to our knowledge, ever been replicated in its entirety, we do not have the necessary data for a bound associated with the R&G column of Table 3.3. We do have such data for its M&C column, however. First, Miller and Charles [1991] report the correlation coefficient between their ratings and the ratings of the same 30 pairs in Rubenstein and Goodenough's experiment to be 0.97. Second, Resnik [1995], who replicated Miller and Charles's experiment (with just 10 subjects), found the correlation between the mean ratings in his replication and those in their experiment to be 0.96. Finally, Resnik also computed the average correlation with the Miller–Charles mean ratings over his 10 subjects to be 0.8848.

While the difference between the (absolute) values of the highest and lowest correlation coefficients in column 2 of Table 3.3 is of the order of 0.1, all of the coefficients compare quite favorably with the above estimates of the upper bound, especially with the last, most relevant, figure. Furthermore, the difference diminishes almost twofold

and differences between the corpora used to obtain the frequency data (Jiang and Conrath, Lin; *see* Section 5.4.1.2). Also, the coefficients reported by Resnik and Lin are, actually, based on 28 out of the 30 Miller–Charles pairs due to a noun missing from Resnik's version of WordNet.

[5]For the sake of convenience, we give absolute values of the correlation coefficients corresponding to Jiang and Conrath's measure, which are negative because the measure returns *distance*, as opposed to *similarity* (*cf* footnote 3).

as we consider the larger Rubenstein–Goodenough dataset. In fact, the measures are divided in their reaction to increasing the size of the dataset: the correlation improves for rel_{HS}, sim_{LC}, and sim_{R} but deteriorates for dist_{JC} and sim_{L}. This division might not be arbitrary: the last two depend on the same three quantities, $\log p(c_1)$, $\log p(c_2)$, and $\log p(lso(c_1, c_2))$ (*see* Equations 2.30 and 2.34).[6] However, with the present amount of evidence, this connection remains hypothetical.

An examination of the graphs in Figures 3.1 and 3.2 gives rise to several more points. Of the five computational measures, the discrete nature of the Hirst–St-Onge and Leacock–Chodorow measures is much more apparent from the graphs than that of the others: *i.e.,* a fixed number of *levels* encompassing a non-trivial number of points can be rather easily distinguished in the plots of the ratings produced by rel_{HS} and sim_{LC}. This, of course, is a result of their being based on the same highly discrete factor: the path length.

As a matter of fact, a more substantial correspondence between the two measures can be recognized from the graphs and explained in the same way. In each dataset, the upper portions of the Hirst–St-Onge ($\text{rel}_{\text{HS}} \geq 150$) and Leacock–Chodorow ($\text{sim}_{\text{LC}} > 4$) graphs look the same: namely, the sets of pairs affording the highest and the second highest values of the two measures are identical. This happens because the sets are composed of synonym and parent-child pairs, respectively.[7]

Further down the Y-axis, we find that the two graphs still mirror each other quite closely in the middle region (2.4–3.2 for sim_{LC} and 90–100 for rel_{HS}) for the Miller–Charles data. For the larger set of Rubenstein and Goodenough's, however, differences begin to surface. The pair *automobile–cushion* (22), for instance, is ranked even with *magician–oracle* (37) by the Hirst–St-Onge measure but far below both *magician–oracle*

[6] In fact, the coefficient for sim_{R}, which depends on one of the three, $\log p(lso(c_1, c_2))$, improves only in the third digit.

[7] In general, the inverse image of the second highest value for sim_{LC} is a proper subset of that for rel_{HS}, for the latter would also include all the antonym and meronym-holonym pairs. The two datasets at hand, however, do not seem to contain any examples from these categories.

(37) and *bird–crane* (42) by Leacock–Chodorow (and, in fact, all the other measures). The cause of such a high ranking in the former case is the following connection present in WordNet:

> automobile/. . . /car HAS-A suspension/suspension system ('a system of springs or shock absorbers connecting the wheels and axles to the chassis of a wheeled vehicle') HAS-A cushion/shock absorber/shock ('a mechanical damper; absorbs energy of sudden impulses').

Since rel_{HS} is the only measure taking into account WordNet relations beyond IS-A (and synonymy), no other measure was able to detect this connection (nor were, in fact, the human judges, whose task was to assess *similarity*, not generic *relatedness*; *see* Section 3.2).

Finally, at the bottom portion of the graphs, the picture becomes very different, since rel_{HS} assigns all weakly-related concepts the value of zero. (In fact, it is this cut-off that we believe to be largely responsible for the low relative ranking of the correlation coefficient for the Hirst–St-Onge measure.) In contrast, two other measures, Resnik's and Lin's, appear to behave quite similarly in the low-similarity region. In particular, their sets of zero-similarity pairs are identical, as the definitions of both include the term $\log p(lso(c_1, c_2))$, which evaluates to zero for the pairs in question.[8] For instance, for the pair *rooster–voyage* (M&C #29, R&G #2),

> cock/rooster ('adult male chicken') IS-A . . . IS-A domestic fowl/. . . /poultry IS-A . . . IS-A bird IS-A . . . IS-A animal/animate being/. . . /fauna IS-A life form/. . . /living thing ('any living entity') IS-A entity ('something having concrete existence; living or nonliving')

while

[8] Again (*cf* footnote 7), the former set actually constitutes a proper subset of the latter, since $\text{sim}_{\text{L}}(c_1, c_2)$ will also be zero if either concept does not occur in the frequency-corpus (*see* Equation 2.34). However, no such examples can be found in the two datasets at hand.

> voyage IS-A journey/journeying IS-A travel/. . . /traveling IS-A change of location/. . . /motion IS-A change ('the act of changing something') IS-A action ('something done (usually as opposed to something said)') IS-A act/human action/human activity ('something that people do or cause to happen').

Entity and act are both 'unique beginners' (*see* Section 2.3.1); hence the sole common subsumer of rooster and voyage (and hence their lso) is the (fake) global root (*see* Section 2.3.3.3), which, in turn, is the only concept whose p is 1. Analogously, although, perhaps, somewhat more surprisingly for a human reader, for the pair *asylum–cemetery* (R&G #16), $\mathrm{sim_L} = \mathrm{sim_R} = 0$, since

> asylum/insane asylum/. . . /mental hospital IS-A hospital/infirmary IS-A medical building ('a building where medicine is practiced') IS-A building/edifice IS-A . . . IS-A artifact/artefact ('a man-made object') IS-A object/inanimate object/physical object ('a nonliving entity') IS-A entity

whereas

> cemetery/graveyard/. . . /necropolis ('a tract of land used for burials') IS-A site ('the piece of land on which something is located (or is to be located)') IS-A position/place ('the particular portion of space occupied by a physical object') IS-A . . . IS-A location ('a point or extent in space').

Looking back at the high-similarity portion of the graphs, but now taking into consideration the rest of the measures, we can make a couple more observations. First, the graphs of all of the measures exhibit a 'line' of synonyms (comprising four points for the Miller–Charles dataset and nine points for Rubenstein–Goodenough) at the top (bottom for Jiang and Conrath's measure), except for Resnik's. In the latter case, $\mathrm{sim_R}(c, c) = -\log p(lso(c, c)) = -\log p(c)$ (*see* Equation 2.18); hence the similarity between a concept and itself may vary from one concept to another. Second, the aforementioned 'lines' are not continuous, as one might expect from the graphs of the human

judgements: for the Miller–Charles set, for instance, the line includes pairs 1, 2, 7, and 8, while missing pairs 3–6. This peculiarity is due entirely to WordNet, according to which *gem* and *jewel* (pair 2) are synonyms, whereas *journey* and *voyage* (pair 3), *boy* and *lad* (pair 4), and even *asylum* and *madhouse* (pair 6) are not:

> lad/laddie/cub/sonny/sonny boy ('a male child (a familiar term of address to a boy)') IS-A boy/male child/child ('a young male person'),
>
> voyage ('a journey to some distant place') IS-A journey/journeying ('the act of traveling from one place to another'),
>
> madhouse/nuthouse/.../sanatorium ('pejorative terms for an insane asylum') IS-A asylum/insane asylum/.../mental hospital ('a hospital for mentally incompetent or unbalanced persons').

— while *magician* and *wizard* (pair 7) are synonyms again.

Although, as we saw above, already for two measures the details of their medium-similarity regions differ, there appears to be an interesting commonality at the level of general structure: in the vicinity of sim = 2, the plots of human similarity ratings for both the Miller–Charles and the Rubenstein–Goodenough dataset display an easily discernible horizontal band that contains no points. For the Miller–Charles data (Figure 3.2), the band separates the pair *crane–implement* (16) from *brother–monk* (14),[9] and for the Rubenstein–Goodenough (Figure 3.1), it separates *magician–oracle* (37) from *crane–implement* (38). On the graphs of computed ratings, to these void strips we can put in correspondence regions with at most a few points (up to 2 for the Miller–Charles set and up to 4 for the Rubenstein–Goodenough set). As we will argue in Section 5.4.2, this commonality may bear more significance than at first appears, as it suggests that, if we

[9] Miller and Charles ordered their pairs according to the opinions of their subjects, except, for some reason, the pairs *lad–brother* (15) and *crane–implement* (16), whose ratings were 1.66 and 1.68, respectively, according to their subjects but 2.41 and 2.37, respectively, according to Rubenstein and Goodenough's subjects.

were to partition the set of all pairs into the related and the unrelated, the boundary between the two subsets, for each measure (and for the human judgements, for that matter), should lie somewhere within these regions.

Chapter 4

Some Applications and Relevant Results

As we argued in Section 1.1, the continuing interest in measuring semantic relatedness can be probably best explained by its wide applicability. Furthermore, for the reasons outlined in Section 3.1, the majority of researchers whose work was presented in Chapter 2, have chosen to test their approaches in the framework of a particular application, thereby either rendering them comparable with others or at least allowing for some performance-related intuition. In this chapter, then, we discuss, in varying degrees of detail, some applications of the methods reviewed earlier as well as the relevant results that experimentation with them has produced.

4.1 Resolution of Word Sense Ambiguity

The task of resolving word sense, or lexical, ambiguity — also known as word sense disambiguation (WSD) or word sense identification — can be viewed as establishment of a correspondence between a use of a word in a text and its appropriate sense in a lexicon. A great many words, in any natural language, have more than one meaning, owing to *polysemy*, *homonymy/homography*, and *categorial ambiguity* [Hirst, 1987], with

some English words' senses numbering in excess of 60 (*e.g.,* the verb *go*) [Amsler, 1980]. As Leacock and Chodorow [1998] point out, "some level of word sense identification is required for virtually all natural language processing applications". The approaches presented below all attempt to tackle this fundamental task, with the help of a measure of semantic relatedness.

4.1.1 Agirre and Rigau

In Agirre and Rigau's method, "given a window size, the program moves the window one noun at a time from the beginning of the document towards its end, disambiguating in each step the noun in the middle of the window and considering the other nouns in the window as context" [Agirre and Rigau, 1996]. For each particular window W with the middle word w, the program computes the Conceptual Density of every nominal concept in WordNet with respect to the senses of the words in W that the concept contains in its subhierarchy (*see* Section 2.3.3.4). "It selects the concept c with the highest Conceptual Density and selects the senses below it as the correct senses for the respective words"[1] — the rest of their senses are then eliminated from further consideration. Unfortunately, both [Agirre and Rigau, 1996] and [Agirre and Rigau, 1997] seem a little unclear as to what *exactly* happens next, but we can imagine the following scenario. If, as a result of the above process, w is down to a single sense, we are done, and the window can advance. Otherwise, we can repeat the process with the remaining senses of the words in W: since there are fewer of them now, the conceptual density values should change (Equation 2.17). If, however, no senses (of any words in W) were eliminated during the

[1] This is the place in Agirre and Rigau's method to which we referred in Section 2.3.3.4 when claiming that their Conceptual Density (2.17) could be used to derive a measure of semantic relatedness. According to the description above, one obvious way to do this is to define

$$\mathrm{rel}_{\mathrm{AR}}(w_1, \ldots, w_m) = \max_{c \in \mathcal{L}} \mathrm{CD}(c, m) \ ,$$

where $w_1, \ldots, w_m$ are the contents of W (including w) and $\mathcal{L}$ is the entire lexicon (in this case, the noun part of WordNet).

last iteration, then any further attempts to disambiguate w (with the current window) are futile, and the word is considered genuinely ambiguous.

Agirre and Rigau [1997] describe an experiment that deployed this algorithm to disambiguate the noun portion of a 2079-word-long text randomly chosen from SemCor [Miller *et al.*, 1993] (a sense-tagged subset of the Brown Corpus). Out of the total of 564 nouns in the text, 464 were found in WordNet, of which 315 were polysemous. The sense tags assigned by the algorithm were compared against the original sense tags contained in SemCor in terms of precision, recall, and coverage.[2] The overall performance was found to be best for the window size of 25, yielding 88.6%, 66.4%, and 58.8% for coverage, precision, and recall, respectively, and 83.2%, 47.3%, and 39.4% if polysemous nouns only were considered.

The algorithm was found to considerably outperform (on the order of 15%) the 'guessing baseline' (selecting senses at random) in precision and give a 10% better coverage than the 'most frequent' heuristic[3] (the precision in this case was about the same).

In a followup study, reported by Agirre and Rigau [1996], four SemCor texts were used, containing the total of 1858 WordNet nouns, of which 1256 were polysemous. The overall coverage, precision, and recall came out between 2% and 5% lower, and the optimal context (window) size was found to vary depending on the genre of the text.

All in all, Agirre and Rigau qualified the results as promising, "considering the difficulty of the task (free running text, large number of senses per word in WordNet), and the lack of any discourse structure of the text".

[2] *Precision* was computed as the ratio of the number of correctly disambiguated nouns to the total number of disambiguated nouns, *recall* as the ratio of the number of correctly disambiguated nouns to the total number of nouns considered, and *coverage* as the ratio of the total number of disambiguated nouns to the total number of nouns considered.

[3] The frequency counts for each sense were collected from the rest of SemCor.

4.1.2 Sussna

In Sussna's [1993] experiments, for a given window of words (terms) $T = \{t_1, t_2, \ldots, t_n\}$, "each combination of n senses across the terms is tried, with one sense chosen at a time for each term". For each such combination, the $\frac{n(n-1)}{2}$ pairwise distances are summed to arrive at an overall value, $H(T)$. If we let $\mathcal{S}$ denote the set of all sense combinations of the terms in T, and $S \in \mathcal{S}$ be a particular such combination (*i.e.,* $S = \{s_1, s_2, \ldots, s_n\}$, where each s_i is a sense of t_i), then "the winning combination" is the $S \in \mathcal{S}$ that produces "the minimal 'energy'"

$$H_{\min}(T) = \min_{S} \sum_{x,y \in S} \mathrm{dist}_S(x, y) \; . \tag{4.1}$$

How exactly the minimal-energy sense combination is used for disambiguation depends on the variety of window, of which Sussna distinguishes several. For an *initial mutual constraint* window, "all of the terms in the window are assigned ... senses at the same time." When working with a *moving mutual constraint* window, only the middle term in the window is assigned its sense on the basis of $H_{\min}$. "Record is kept of the winning sense, but when that term plays a role other than 'middle term', its senses are allowed to fully vary", thus giving a middle term "full benefit of both previous and subsequent context. All senses of surrounding terms are considered, not just their winning senses." In *frozen past* approach, only the last term in the window is assigned its sense. This strategy results in essentially linear-time processing, as "there are only as many 'combinations' to try as there are senses of the single term being disambiguated." Finally, various ways of combining these approaches are possible (*e.g.,* a small set of initial terms is processed with mutual constraint, and later terms are then processed with a moving frozen-past window).

In the main evaluation, five documents from the *Time* magazine article collection were considered, and the output of the "semantic distance software" was compared with

that of "chance software"[4] and human disambiguators.[5] The comparison was conducted by means of a couple of non-standard metrics invented by Sussna himself. His method's performance fell almost exactly in the middle between the performance of the chance software and that of human disambiguators.

An interesting fact, however, is that Agirre and Rigau, having noticed a certain degree of similarity between their ideas and Sussna's, replicated his experiment and found their precision (*see* footnote 2 on page 49) to be 60.1% against his 52.3% [Agirre and Rigau, 1996].

4.1.3 Leacock and Chodorow

Leacock and Chodorow [1998] conducted a "preliminary" investigation into using WordNet-based similarity as an aid to a statistical local-context classifier.

A typical methodology is to train a classifier on contexts that contain a polysemous word of interest in a known sense. As Leacock and Chodorow point out, a fundamental problem with this approach is the sparseness of training data: since they have to be hand-disambiguated, "the task of collecting large training sets for each sense of each polysemous word is simply not feasible". Leacock and Chodorow's idea is then to use similarity to "fill in gaps in a sparse training space", relying on the conjecture that "semantically similar words should provide similar contextual clues". For example, if *baseball* proves to be a good discriminator for a particular sense of the verb *play*, then so should be words semantically similar to it, such as *hockey*, *football*, or *soccer*, even if they are not initially a part of the training space.

Leacock and Chodorow tackled the problem of discerning among four senses of the verb *serve* ('serve a function or purpose', 'provide a service', 'supply with food or drink',

[4] This is the same as the 'guessing baseline' in Agirre and Rigau's experiments (Section 4.1.1).

[5] The human disambiguators were given roughly the same information as the semantic distance software: the list of nouns from the documents, with each noun accompanied by its synsets, their hypernym synsets, and a gloss if available.

and 'hold an office') in all of their experiments. Sentence-length contexts for the verb and its morphological variations were collected from the 25-million-word APHB corpus and the 1987 edition of *Wall Street Journal* of a comparable size. This resulted in a corpus containing at least 350 sentences for each of the four senses of *serve*,[6] which were used for building both training and testing sets for the experiments.

Leacock and Chodorow's original classifier analyzed the local context in terms of its part-of-speech, open-class-item, and closed-class-item composition. During the training phase, three frequency distributions were derived. Given a verb-occurrence v_i of *serve* in a test set, a score, based on the likelihood of v_i's local context according to these distributions, was computed for each of the four possible senses of v_i. The sense with the highest score was then selected.

For the purposes of evaluation, senses returned by the classifier were compared with those assigned by human judges. With the optimal window size of ± 2, ± 6, and ± 2 positions[7] for part-of-speech, open-class-item, and closed-class-item information, respectively, the average performance, in terms of correctly identified senses, was 75% for training sets of size 50, 79% for training sets of size 100, and 83% for training sets of size 200.

Before adding a semantic component to their classifier, Leacock and Chodorow decided to experiment with similarity as a sole means of word sense identification. They formed "separate left and right context sets, corresponding very roughly to the subject and complement of *serve*", by extracting the noun immediately preceding and the noun immediately following each verbal instance of *serve* in the training set (and accounting for passivization as necessary). Two semantic similarity measures, Leacock and Chodorow's (Section 2.3.3.3) and Resnik's (Section 2.4.1), were run on the training and testing con-

[6] Each occurrence of the verb *serve* was tagged with a WordNet sense by two people, and only the sentences on which both taggers agreed were included in the final corpus.

[7] All sentences in Leacock and Chodorow's experiments were preprocessed with Brill's [1994] part-of-speech tagger. A *position* can then be defined as any syntactic unit awarded a separate tag (these would include compound nouns and punctuation).

text sets. Since, as preliminary studies indicated, the complement of a verb appears to have a higher predictive value than the subject, the right context was weighted over the left context, resulting in the following algorithm:

1. the maximum similarity values between the right-context noun and the nouns in all four right-context training sets were computed, and the sense with the highest value was selected;

2. if a single sense could not be selected because of a tie or if the test occurrence simply had no right context, the maximum similarity values were computed in an analogous manner for the left context and the sense with the highest value was chosen;

3. if two or more senses were tied for the first place or there was no left context, DON'T KNOW would be returned.

The algorithm was tested with the training set sizes of 10, 25, 50, 100, and 200. For all of these, both similarity measures performed better than chance (the lowest average percentage correct, delivered by Resnik's measure with training sets of 10 sentences, being 35% versus 25% for chance). Comparatively, Leacock and Chodorow's measure outperformed Resnik's for smaller training sets in terms of percentage correct (2–5% difference), but the latter had fewer errors (0–8% difference). For 200-sentence training sets, Resnik's measure fared slightly better than Leacock and Chodorow's. Overall, however, the percentage of incorrect sense-assignments was rather high (up to 36% for Leacock and Chodorow's trained on 10 sentences). In order to rectify that, Leacock and Chodorow tried running the system with both measures at once, choosing a sense only if it had the highest ranking according to both. This brought down the error rate considerably (10–15%) but did so at the expense of recall (the percentage of DON'T KNOWs increased by 20–27%).

As a test of the generalizing power of similarity, Leacock and Chodorow conducted another experiment, in which they compared the performance of a sense-identification algorithm based on exact base-form matches (which were found highly reliable by a number of researchers) with that of an algorithm combining exact matches with similarity-matches. According to the first algorithm (which we will call *EM*), a sense was selected only if a test occurrence of *serve* had exactly the same noun to its right or to its left (in this order of precedence) as an occurrence in the training set. In the second algorithm (we will refer to it as *EM+*), after a context had been examined for an exact match and none found, the similarity measures were consulted, and, if they agreed on the same sense, that sense was chosen.[8]

The first algorithm achieved its best performance when trained on 200 sentences, correctly identifying, on average, 47% of the test occurrences and returning DON'T KNOW for 42%. The best performance of the second algorithm was 56% correct and 30% DON'T KNOW (for the same training set size). In general, "the exact-match-plus-semantic-similarity approach more than doubled the effective size of the training set". That is, the second algorithm consistently performed better than the first algorithm with twice the training data. For instance, the second algorithm correctly identified 54% of the test occurrences of *serve* when trained on only 100 sentences, thereby surpassing the first algorithm's 47% resulting from training on 200 sentences (*see* above). Similarly, while the first algorithm achieved the accuracy of 39% after training on 50-sentence sets, the second algorithm scored 43% with half of the training.

As an example of the similarity-induced "expansion" of the training space, nouns such as *tart*, *refrigerator*, and *caviar*, occurring in test contexts but not in the training sets, were found similar to the training context associated with the sense 'supply with food or drink' of the verb *serve* by both similarity measures, and hence the sense was correctly

[8]Compared with the algorithm described on the previous page, *EM+* has the benefit of considering words that are not in WordNet during its exact-match phase.

determined by the second algorithm.

Since 56% was still a long way from 83%, Leacock and Chodorow concluded that even the exact-match coupled with semantic similarity is not adequate as a stand-alone classifier[9] and proceeded to combine the similarity-matching with their statistical local-context classifier. This was done in a fashion similar to the *EM+* algorithm: the open-class component of a given test context was compared with the training data; if a similar (according to both measures) context was found, it was substituted for the training context, and the revised sentence was then submitted to the statistical module of the classifier. For example, the words *sauerbraten* and *dumpling* were found to be similar to *dinner* and *bacon*, respectively (both from the training corpus), so the test sentence *Sauerbraten is usually served with dumplings* was replaced with *Dinner is usually served with bacon* by the similarity-module.

Augmenting the statistical local-context classifier with a similarity component resulted in "a small but consistent improvement in the classifier's performance". For training sets of size 200, the difference in the percentage correct was 0.6% (83.1% *vs* 82.5%), but it increased as the training set size decreased, reaching 3.5% for 10 sentences (59.4% *vs* 55.9%). The results should therefore be considered satisfactory, since, as Leacock and Chodorow argue, it is precisely small training sets that are practical when it comes to the task of collecting training data for a large number of words.

4.1.4 Lin

Lin also used his measure (2.34) in research on using local context for word sense disambiguation [Lin, 1997b].

In contrast with the common motto that "two occurrences of the *same* word have *identical* meanings if they have *similar* local contexts", the intuition behind Lin's method

[9] "This is hardly suprising," they write, "as the local context needed for disambiguating verbs includes more than just [their] arguments."

is that "two *different* words are likely to have *similar* meanings if they occur in *identical* local contexts".

The general idea of the method is first to compile a database of local contexts (defined in terms of intrasentential syntactic dependencies; *see* [Lin, 1997b] for details); given that, for each ambiguous word w we can extract *selectors* (the words occurring in identical context in the database) and then, with the aid of the semantic distance function, choose the sense of w that maximizes the similarity between the word and its selectors.[10]

Interestingly enough, Lin also used his similarity measure in performance evaluation of the above disambiguation method. Cued by the observation that given "a list of senses in a general-purpose lexical resource, even humans may frequently disagree with one another on what the correct sense should be", he relaxed the criterion of correctness, counting s_{answer} as correct as long as it is "similar enough" to the sense tag s_{key} in SemCor. The most relaxed interpretation of "similar enough" was taken to be $\mathrm{sim_L}(s_{answer}, s_{key}) > 0$ — which is true as long as s_{answer} and s_{key} have a common subsumer in WordNet (*e.g.,* they are both locations, living things, etc.). Naturally, the strictest interpretation is $\mathrm{sim_L}(s_{answer}, s_{key}) = 1$, which is only true if s_{answer} and s_{key} are identical. The compromise between the two that Lin came up with was $\mathrm{sim_L}(s_{answer}, s_{key}) > 0.23$, where the right-hand side is "the average similarity of 50,000 randomly generated pairs (w, w') in which w and w' belong to the same *Roget's* category".

Lin used a 25-million-word *Wall Street Journal* corpus to construct his local context database and the 'press reportage' part of SemCor (about 14,000 words with 2,832 distinct polysemous nouns) as a test set. Compared with the baseline strategy of always choosing the WordNet-sense most frequent in SemCor, his method scored 56.1% *vs* baseline 58.9% for the strictest criterion of correctness, 68.5% *vs* 64.2% for the intermediate one, and 73.6% *vs* 67.2% for the most relaxed criterion. Hence, whereas the algorithm actually does a little worse than the baseline when it comes to choosing *the* right sense, once the

[10] The exact methodology of the last step falls outside of the scope of this report.

correctness criteria are relaxed, its "performance gain" is considerably larger than that of the baseline method. In other words, when the algorithm does make mistakes, "the mistakes tend to be closer to the correct answer" than the most frequent sense is.

4.1.5 Okumura and Honda

Resolution of word sense ambiguity is also one of the applications investigated by Okumura and Honda [1994]. In their framework, lexical disambiguation of a word consists in deciding on its most likely thesaural category number. Since (recall from Section 2.2.3) two words can enter into the same chain if and only if they belong to the same category of *Bunrui-goihyo*, a word's sense is uniquely determined by the lexical chain the word is added to.

In order for lexical chains "to function truly as local context", Okumura and Honda arrange them in the order of *salience* that is based on the chain's recency and length: longer and more recently updated chains are considered to better represent the topic in the neighborhood. The key steps of the resulting algorithm are as follows:

1. select candidate words (nouns, verbs, and adjectives (with some exceptions));

2. check for intra-sentential lexical cohesion, *i.e.,* attempt to build new chains out of the candidate words within a sentence;

3. try to fit the remaining candidate words into existing lexical chains in order of salience (which is updated along the way).

For the purposes of evaluation, the system was run on five texts taken from Japanese language examination questions. The performance was calculated as the quotient of the number of *correctly disambiguated* words by the number of *ambiguous* (but correctly segmented) words. The system's average performance of 63.4% is considered promising by Okumura and Honda, for they acknowledge the relative naïveté of their method (in

both the salience determination mechanism and the knowledge sources employed) and they see immediate ways of improving it (for instance, by making use of the Japanese topical marker '*wa*', etc.).

4.2 Identifying the Discourse Structure

4.2.1 Okumura and Honda

The second application of Okumura and Honda's lexical chains is based on the observation that "when a lexical chain ends, there is a tendency for a segment [of text] to end" and "if a new chain begins, this might be an indication that a new segment has begun". Following Passonneau [1993], they introduce 'boundary strength' $w(n, n+1)$, for the point between sentences n and $n+1$, computed as the sum of the number of chains ending at sentence n and the number of chains commencing at sentence $n+1$.

Again, five texts from a Japanese language examination were used for evaluation. (This time, the exam questions specifically asked to partition a text into a given number of segments.) The system's average recall and precision rates came out to be 52% and 25%, respectively.[11] While the results were found unsatisfactory overall, the proposed measure of boundary strength is described as "promising and useful as a preliminary one". Okumura and Honda report that work on refining the method by taking into consideration additional factors, such as chain length, lexical clues, etc., had begun and already yielded a certain degree of improvement. (We refer the reader to [Okumura and Honda, 1994] for further discussion.)

[11] *Recall* was calculated as the proportion of correctly identified boundaries in the number of boundaries given in question; *precision* was calculated as the proportion of correctly identified boundaries in the total number of generated boundaries.

4.2.2 Morris and Hirst

As we have alluded to earlier, Morris and Hirst [1991; Morris, 1988] used their five thesaural relations for building *lexical chains*: sequences of words in text that "bear a cohesive relation" to one another, thereby spanning "a topical unit of text" and contributing to "the continuity of lexical meaning".

Following Halliday and Hasan, "repetitive occurrences of closed-class words such as pronouns, prepositions, and verbal auxiliaries" did not participate in chain construction. Also, high-frequency words like *good, do,* and *taking* (with some exceptions) would not normally enter into lexical chains. So, in passage (1) [Morris and Hirst, 1991], only the italicized words would be considered as lexical chain candidates.

(1) My *maternal grandfather lived* to be *111. Zayde* was *lucid* to the *end*, but a few *years before* he *died* the *family assigned* me the *task* of *talking* to him about his *problem* with *alcohol*.

Five texts (totaling 183 sentences) "from general-interest magazines" were used in Morris and Hirst's experiments. The lexical chains built in accordance with the algorithm of Section 2.2.2 were compared with those constructed by the authors on the basis of their intuition (*i.e.,* common sense and knowledge of English). The main result reported by Morris and Hirst [1991] was that their algorithm was able to spot "well over 90% of the intuitive lexical relations".

Morris and Hirst found the principal hindering factor in the algorithm performance to be "missing sources": "general semantic relations between words of similar 'feeling'", "situational knowledge", and "specific proper names" — all of which "are certainly contained in one's 'mental thesaurus'".

The 'real-world' application investigated by Morris and Hirst was the use of lexical chains as an aid in identifying structural units of text. Driven by the intuition that "lexical cohesion in text should correspond in some way to the structure of text" and the

fact that lexical chains, in essence, represent "patterns of lexical cohesion", they compared the "lexical chain structure of text" with "a good standard approach" — the *intentional structure* of Grosz and Sidner [1986]. The result of this comparison was their discovery of a close correspondence between the two techniques, which was considered especially important since Grosz and Sidner gave no method for computing "the intentions or linguistic segments that make up the structure" that they proposed.

Unfortunately, due to the lack of an on-line copy of modern *Roget's*, Morris and Hirst were not able to implement their lexical chaining algorithm.

4.3 Text Summarization, Annotation, and Indexing

4.3.1 Barzilay and Elhadad

Text summarization — the process of "condensing a source text into a shorter version preserving its information content" [Barzilay and Elhadad, 1997] — can serve several purposes and assume different forms. Production of a high-quality 'informative summary' of an arbitrary text (to be used in a literature survey, for instance) remains a challenging problem, for it requires a full understanding of the text. 'Indicative summaries' (to be used, for instance, "to quickly decide whether a text is worth reading" [ibid.]), on the other hand, can be obtained by applying less powerful methods. One such method, deploying *lexical chains* (*see* Section 4.2.2), is presented by Barzilay and Elhadad [1997].

Following Sparck Jones [1993], summarization can be regarded as a multistep process. *First*, a representation of the source text is constructed. *Second*, the summary representation is formed from the source-text representation. *Finally*, the output summary text is synthesized. One relevant question in this framework, then, concerns the types of information (linguistic, domain, communicative) to be included in the source-text representation.

Early summarization systems [Luhn, 1968] were based solely on the intuition that

the most important concepts in the text are given by the most frequent words. The resulting representation, a frequency table of text words, thus entirely ignored any kinds of connections between words. At the other extreme lies the use of a detailed semantic representation, such as that produced by MUC-style systems [McKeown and Radev, 1995]. In contrast with these techniques, Barzilay and Elhadad's primary goal is to find "a middle ground for source representation": it should be "rich enough to build quality indicative summaries" and yet be easily extractable from an arbitrary text. As mentioned above, they propose using lexical chains as the basis for such a representation.

The key step in any procedure for constructing lexical chains is finding an appropriate chain for a given word, a process tantamount to (partially) disambiguating the word in context. Both Morris and Hirst [1991] and Hirst and St-Onge [1998] adopt a greedy approach to disambiguation, which, as Barzilay and Elhadad argue, has certain drawbacks. To avoid these, Barzilay and Elhadad, who employ a slightly modified form of Hirst and St-Onge's measure of semantic relatedness (Section 2.3.2.2), have opted for the concurrent development of all possible interpretations (with threshold-regulated pruning, if necessary): instead of placing a word in the first candidate chain available, all the alternatives with respect to chain inclusion are maintained, and, in the end, the strongest interpretation (one whose graph has the greatest number of edges) is selected.[12]

To implement the second stage of the summarization process, there needs to be a way to discriminate among the chains constructed in the previous step. The chain *length* and *homogeneity* (*see* [Barzilay and Elhadad, 1997] for details) are currently used for this purpose, but the search for good measures of the *strength* of a chain is reported to be in progress.

Finally, in order to generate the text of a summary, full sentences corresponding to

[12]Barzilay and Elhadad's algorithm differs from Hirst and St-Onge's lexical chainer in a couple of other respects as well. For instance, Barzilay and Elhadad use a POS-tagger and a shallow parser to identify nouns and noun compounds and apply Hearst's [1994] text segmentation technique to break a text into units for which chains are built and later merged.

the strong chains are extracted from the source. A few alternative methods for this step are also being investigated.

The principal problem areas identified by Barzilay and Elhadad include the granularity of lexical units selected as summary constituents, anaphora resolution, and control over the summary length and level of detail. "The method ... is obviously partial in that it only considers lexical chains as a source representation, and ignores any other clues that could be gathered from the text," they write. However, a preliminary evaluation indicated that the quality of summaries produced by the method is superior to that of summaries produced by presently used commercial systems (such as WWW search engines).

4.3.2 Green

Another interesting application of the semantic relatedness also using the lexical chaining methodology is Green's **HyperTect** system [1997b, 1997a] for automatic construction of hypertext links within and between online newspaper articles.

Unlike most other proposed methods for automatic hypertext construction, based on term *repetition*, or *lexical equivalence*, Green's approach relies on term *relatedness* and, in particular, uses Hirst and St-Onge's measure from Section 2.3.2.2.

For the purposes of introducing links within an article, Green follows Morris and Hirst's [1991] (Section 4.2.2) intuition that "the parts of a document that have the same lexical chains are about the same thing" [Green, 1997a].

Since a unit of text (a paragraph, in this case) can have several chains associated with it, the first step of the method is to rank their relative importance. This is done by computing *chain densities*: if $w_{c,p}$ is the number of words from paragraph p that appear in chain c and w_p is the total number of content words in p, then the density of chain c

in paragraph p is simply

$$d_{c,p} = \frac{w_{c,p}}{w_p} \,. \tag{4.2}$$

With the help of Formula 4.2, an n-paragraph text that gives rise to m lexical chains can be represented by n m-dimensional *chain density vectors*.[13] Their pairwise proximities can then be computed by vector-space methods (*e.g.,* Dice coefficient or Mean Euclidean distance; *see* [Green, 1997b], page 39) resulting in a distribution (with $(n-1)^2$ points). If two paragraphs are closer to each other than a threshold, given in terms of a number of standard deviations, they should be linked (*see* [Green, 1997b] for details).

Because two documents do not share chains and chain merging would be inefficient, a different methodology, largely reminiscent of IR, is adopted for the task of constructing inter-article links. Each document is represented by two vectors, the *member synset* vector and the *linked synset* vector, whose size equals the number of nominal synsets of WordNet. The coordinate of the *member synset* vector that corresponds to a given synset will contain a weight based on the number of occurrences of that synset in the chains built for the document. The coordinate of the *linked synset* vector that corresponds to a given synset will contain a weight based on the number of occurrences of the synsets that are one link away in the chains built for the document. In either case, the weight also depends on the frequency of the synset in the entire collection of documents, the size of the collection, and other factors (*see* [Green, 1997a] for details).

The similarity between two documents can then be computed as the sum of three similarities, *member-member*, *member-linked*, and *linked-member*, each of which is measured by taking the cosine of the angle between the respective vectors. If the value of the similarity exceeds a given threshold, a link is placed between the documents.

The main evaluation of HyperTect involved analyzing the performance of a group of 23 subjects on a browser-assisted question-answering task. The hypothesis to be tested

[13] If a paragraph p' does not contribute to a chain c', then $d_{c',p'}$ is 0. Hence, for shorter and/or more cohesive paragraphs, density vectors will be fairly sparse.

was whether "a semantics-based approach to hypertext link generation" is superior to "a strict term-repetition approach" [Green, 1997b].

The experimental database contained over 30,000 newspaper or magazine articles from the TREC corpus [Harman, 1994]. Of these, 1996 documents bore relevance to the three topics chosen to develop three questions (one question per topic), such as "List the names of as many people as you can find that are identified as 'terrorists'. You should *not* include the names of terrorist groups." The remaining documents (relevant to the other 47 topics) were selected at random.

The database was submitted to HyperTect (*HT*) and to a system called **Managing Gigabytes** (*MG*) [Witten *et al.*, 1994] that represented the competing lexical-equivalence–based method. Subsequently, in order to reduce the size of the experiment, the two sets of links were combined, with the common links excluded.[14] (Intra-article links were also included, even though they did not have an *MG* counterpart.)

Each subject was then given the three questions and asked to find answers by navigating through the hypertext. While the subjects were, naturally, not aware of the underlying dichotomy of the inter-article links, the system kept track of the number of links of each type (*HT*, *MG*, and intra-article) followed by each user. Hence, a correlation could be sought between the link-type ratio and the success rate, and, if, for instance, it could be shown that the subjects were more successful as they followed more *HT* links, the superiority of the *HT* method over *MG* could be concluded.

Unfortunately, Green was not able to reach such a conclusion in general. While, among the inter-article links, the subjects exhibited "a slight bias" for *HT*, having followed 52.1% *HT* links versus 47.9% *MG* links,[15] this difference was found statistically insignificant ($p < 0.1$). When the subjects were divided into two categories, the *High*

[14] "By leaving them out," Green writes, "we test the differences between the methods rather than their similarities."

[15] Of the available links, 50.4% were *MG* and 49.6% *HT* links.

Web group and the *Low Web* group, according to their 'browsing skills',[16] however, it was discovered that the High Web group, who found significantly ($p < 0.01$) more correct answers than the Low Web group, followed statistically the same number of *MG* links as but significantly ($p < 0.01$) more *HT* links than the Low Web group. As regards intra-article links, their presence was found inconsequential for the task of finding correct answers. However, they were acknowledged as helpful for general navigation by the Low Web group.

Overall, Green concluded that further evaluation is required but expressed his belief that "there are several implementation factors that, when remedied, will produce a significant result" for his system [Green, 1997b].

4.3.3 Kazman et al.

A series of works by Kazman and his colleagues [Kazman *et al.*, 1995, Kazman *et al.*, 1996, Al-Halimi and Kazman, 1998, Kominek and Kazman, 1997] describes a project directed towards creating and perfecting a system, named **Jabber**, for indexing videoconferences and videotaped meetings.

As Kazman *et al.* [1995] note, capturing audio (what people say), video (what people see), and computer-application (what people do) information streams during videoconferences creates the possibility of using meetings as archives of information. However, "data capture is only one part of the process in creating repositories out of meetings. The data also needs to be appropriately structured and indexed so that it can be later queried and retrieved." Of a variety of forms of indexing mentioned in [Kazman *et al.*, 1995], one that interests us is what they refer to as "indexing by actual content": a speech recognition system is applied to the stored audio track, and the resulting text-based records of meeting are indexed (*see* below) and then (along with some other information, such as

[16] The *High Web* group comprised those who indicated that they use the WWW at least three times a week.

time and speaker) merged back into the original audio/video streams as annotation.

Since "simply recording the words which meeting participants say does not create a meaningful index", Kazman and colleagues decided to use a variant of lexical chaining technique as their tool in identifying meeting topics, or *themes*. Their *lexical trees* are, roughly speaking, a two-dimensional variation on Hirst and St-Onge's lexical chains, organized in such a way that the theme word of a piece of discourse ends up being placed at the top (root) of the corresponding tree (*see* [Al-Halimi and Kazman, 1998] for details). The software implementation used in constructing lexical trees, **LexTree**, is based on the program **LexC** written by St-Onge [1995] and thus uses a similar word relatedness measure to the one described in Section 2.3.2.2.

Addressing the performance of LexTree, Kazman *et al.* note that "the results were encouraging as far as the speed of theme generation and number of themes created" [Kazman *et al.*, 1995]. The outcome of a preliminary study aimed at verification of the "usability of lexical trees for automatic indexing of arbitrary text", in which tree structures developed by LexTree for a journal article were compared to those developed by human subjects, was also found very satisfactory [Al-Halimi and Kazman, 1998, Kazman *et al.*, 1996]. Nonetheless, the most recent work in the series, [Kominek and Kazman, 1997], reports a shift from lexical trees to a new derivative of lexical chains, *concept clusters*. The exact methodology of concept-cluster construction, however, still appears to be in development.

We conclude this subsection by citing Kazman and colleagues' [1996] words that emphasize the utility of lexical trees (and, therefore, indirectly the lexical relatedness measure incorporated therein): "Jabber's efficacy rests primarily on the success of lexical chaining as an information retrieval mechanism".

4.4 Lexical Selection

4.4.1 Wu and Palmer

Having defined the similarity measure in a conceptual domain (Equation 2.11, Section 2.3.3.2), Wu and Palmer [1994] propose to define similarity between "two verb meanings, e.g., a target verb and a source verb ... as a summation of weighted similarities between pairs of simpler concepts in each of the domains the two verbs are projected onto". Formally,

$$\mathrm{sim}_{\mathrm{WP}}(v_1, v_2) = \sum_i W_i \times \mathrm{sim}_{\mathrm{WP}}(c_{i,1}, c_{i,2}) \; . \tag{4.3}$$

Unfortunately, the authors omit details regarding the method of choosing the weights in the above equation. Nonetheless, they do report having implemented a prototype lexical selection system called **UNICON**, in which the described measures of similarity play a leading role in finding a felicitous rendition of a given verb in another language.

In Wu and Palmer's experiments, UNICON was trained on 100 sentences from the Brown Corpus and subsequently tested on several subsets of another 300 sentences. The system's translation success rates ranged from 31% to 99.45%, depending on the complexity of test sets (*e.g.,* whether sentences contained non-concrete objects, metaphors, etc.) and the complexity of concept representation (*e.g.,* whether the meanings of verb arguments had been included, etc.).

The translation quality was found to be generally better than that of the commercial English-Chinese MT system TranStar, and the approach was concluded to be promising overall. One drawback of UNICON that caught our attention, however, is the fact that the verb representations it bears on all have to be encoded by hand. As a consequence, only 21 English verbs were used in Wu and Palmer's experiments.

4.5 Information Retrieval

4.5.1 Rada et al.

For a query represented as a set of terms $Q = \{t_1^Q, \ldots, t_m^Q\}$ and a document represented as the set of its indexing terms $D = \{t_1^D, \ldots, t_n^D\}$, where all t_i^Q's and t_j^D's are terms from the MeSH thesaurus (*see* Section 2.3.2.1), Rada and colleagues [Rada *et al.*, 1989, Rada and Bicknell, 1989] defined, using their inter-term distance $\text{dist}_{\text{Retal}}(t_i, t_j)$ (Equation 2.7), the distance between the query and the document as the mean path-length between all pairs of document index and query terms:

$$\text{DISTANCE}(D, Q) = \frac{1}{mn} \sum_{t_i \in D} \sum_{t_j \in Q} \text{dist}_{\text{Retal}}(t_i, t_j) \; . \tag{4.4}$$

In a series of experiments, they then compared the performance of DISTANCE on the task of ranking document-query matches to that of human experts.[17]

Referring the reader to [Rada *et al.*, 1989, Rada and Bicknell, 1989] for a detailed discussion of the results, we will limit ourselves to quoting the following paragraph from the conclusion of [Rada and Bicknell, 1989]: "We initially applied DISTANCE to documents and queries with the expectation that the ranking of documents which it produced would compare poorly to rankings produced by people. However, the algorithm performed surprisingly well. The extent to which the performance of DISTANCE + MeSH simulates the performance of people depends on the meaningfulness of the BT [BROADER-THAN (Section 2.3.2.1)] relations in MeSH."

[17] As it was considered impractical to calculate distances between a query and all of Medline's five million documents (*see* Section 2.3.2.1), Rada *et al.* decided to first give the query to the database's own searching engine and then have their system and human judges rank the relevance of the retrieved documents to the query.

4.5.2 Richardson and Smeaton

Richardson and Smeaton [1995b] describe another method of computing similarity between a query and a document in the framework of Knowledge-Based Information Retrieval (KBIR). While it is not "an entirely new concept", they note that almost all KBIR systems to date operate in very specific and narrow domains (*cf* Rada *et al.*'s system above) and, therefore, define the objective of their research as the development of a domain-independent KBIR system that uses "an automatically constructed KB containing an entry for all concepts found in everyday language" and a similarity function operating on that KB. The actual document retrieval would then consist in constructing a KB-representation of both a document and a query and comparing these representations using the similarity function.

Richardson and Smeaton's experimental KB consisted of a number of "hierarchical concept graphs (HCG)" automatically constructed from WordNet data files, and two different similarity measures were tried out: Resnik's information-based measure (Section 2.4.1) and a measure referred to as the "conceptual distance estimator". They mention that the latter was derived from the work of Rada *et al.* (*see* Section 2.3.2.1), but differed from the original in that it made use of edge-weighting present in the KB. They also remark that their edge weighting scheme takes into account "the density of the HCG" at a particular point, "the depth in the HCG, and the strength of connotation between parent and child nodes". However, no further details (nor formulas and the like) are given.

Richardson and Smeaton benchmarked their systems (using the two similarity functions) against a "performance-enhanced ... variation of a standard *tf*IDF* system". A conventional IR approach was first applied to 12 randomly chosen TREC-2 queries and the WSJ segment of the TREC database. The top 1000 documents it retrieved for each query then became the test sets. The documents in these test sets were subsequently ranked by each of the three systems according to their similarity to the appropriate

queries and finally compared to one another.

In Richardson and Smeaton's own admission, the results of the comparison were somewhat disappointing: the *tf*IDF*-based system considerably outperformed both of the semantics-based systems in recall as well as precision. However, they write, "this negative result should not be seen as wholly negative but as offering promise". They argue that the poor performance of the semantics-based systems may have been partly caused by certain specifics of both the TREC corpus contents and the benchmarking scheme (namely, "there are many occurrences of proper nouns in TREC queries which do not occur in WordNet" and the TREC ranking mechanism "has been criticized as not favoring approaches which do not retrieve based on word string matching") as well as by lack of fine-tuning of their overall implementation. The basic strategies were hence concluded to be "certainly worth pursuing".

4.6 Word Prediction

4.6.1 Kozima and Ito

Kozima and Ito [1997] tested their method of measuring semantic distance (Section 2.1.3) on the task of word prediction, *i.e.,* predicting the words that are likely to follow in a text by treating a preceding portion of the text as a context.

The distance $\mathrm{dist}_{\mathrm{KI}}(w, w'|C)$ between a pair of words w, w' in context C (Equations 2.4–2.6), can be trivially extended to the distance $\overline{\mathrm{dist}_{\mathrm{KI}}}(w, S|C)$ between a word w and a bag of words S as follows:

$$\overline{\mathrm{dist}_{\mathrm{KI}}}(w, S|C) = \frac{1}{|S|} \sum_{w' \in S} \mathrm{dist}_{\mathrm{KI}}(w, w'|C) \,, \tag{4.5}$$

where $|S|$ stands for the number of words in S.

As a special case, we can compute the distances $\overline{\mathrm{dist}_{\mathrm{KI}}}(w_i, C|C)$, or simply $\overline{\mathrm{dist}_{\mathrm{KI}}}(w_i, C)$, for all words w_i of our vocabulary V, sort the contents of V in order of increasing value

of the distance, and then pick the first k words to form the set $C^+(k)$. That is, formally, $C^+(k) = \{w_{i_1}, \ldots, w_{i_k}\}$ if $\overline{\text{dist}_{\text{KI}}}(w_{i_1}, C) \leq \overline{\text{dist}_{\text{KI}}}(w_{i_2}, C) \leq \ldots \leq \overline{\text{dist}_{\text{KI}}}(w_{i_k}, C) \leq \ldots \leq \overline{\text{dist}_{\text{KI}}}(w_{i_{|V|}}, C)$. The set $C^+(k)$ thus contains the k words closest to C in the vocabulary.

Let us now represent a text as a sequence of words $w_1^N = \langle w_1, \ldots, w_N \rangle$. If, for a word w_i and some constant length δ, the preceding text pre(i) is defined as $w_{i-\delta+1}^i$ and the succeeding text suc(i) is defined as $w_{i+1}^{i+\delta}$, then the performance of predicting the contents of suc(i) based on pre(i) can be evaluated as follows:

1. Sort V with respect to $C = \text{pre}(i)$.

2. For every $w \in \text{suc}(i)$, find the minimum integer value $k(w)$ such that $w \in C^+(k(w))$.

3. If $\bar{k}$ is the average value of $k(w)$ across the suc(i), then take

$$\text{perf}(i) = \frac{|V|/2 - \bar{k}}{|V|/2} \tag{4.6}$$

   to be the performance indicator.

4. If perf(i) $\gg 0$,[18] the word prediction can be considered successful in comparison with that on a *random text*, that is a text "in which words appear at random, though the probability of word occurrence is just same as that in normal texts" (Hideki Kozima; personal communication).[19]

Kozima and Ito used O. Henry's short story "*Springtime à la Carte*" ($N = 1620$) with $\delta = 25$ in their experiment. They computed the values of perf(i) for all word positions $i \in [25, 1595]$ to obtain the average performance indicator of 0.321916. This figure indicated reasonable success of the word-prediction method, but not to the degree expected. When Kozima and Ito plotted the values of perf(i) against i, however, they

[18] As can be seen from Equation 4.6, the range of perf(i) is $[-1, 1]$.

[19] "You can make a random text by shuffling word order of a normal text (which is long enough). Such a text no longer has local semantic structure that helps us predict the succeeding words." (Hideki Kozima; personal communication)

discovered that, along with peaks (sometimes reaching beyond 0.8), the graph had a number of dips, which, upon examination, were found to correspond closely to the scene boundaries of the text identified by human subjects in an independent experiment. Since, at a scene boundary, "pre(i) and suc(i) become semantically different", it was concluded that the performance measure (4.6) is simply not sophisticated enough to account for this phenomenon.

Kozima and Ito name speech recognition as a likely area for the real-world application of word prediction. They also suggest that their measure (4.5) should be well-suited for contextual word-sense disambiguation as well as many other NLP tasks.

Chapter 5

Malapropism Correction in Free Text

5.1 Automatic Spelling Correction

In her definitive, authoritative survey of techniques for automatically detecting and correcting word-errors in text, Kukich [1992] identified three principal areas of research: nonword error detection, isolated-word error correction, and context-dependent word error correction.

The first area concerns efficient identification of strings that do not constitute valid words of a natural language (e.g., $*prspective$). The main body of work in the area was done throughout the 1970s and in the early 1980s, converging on two techniques: dictionary lookup (checking a given string against a lexicon) and n-gram analysis (examining the probabilities of n-letter substrings of a word in a precompiled statistical table).

Research in the second area began as early as the 1960s and has continued into the present. According to Kukich [1992], the problem of isolated-word error correction can be broken into three subproblems: detection of an error (as above), generation of candidate corrections (e.g., *perspective* and *prospective* for $*prspective$), and ranking of the

candidate corrections (in the order of likelihood of being the intended word). Indeed, she notes, most techniques tackle the subproblems by means of separate processes executed in sequence. "A dictionary or a database of legal n-grams" is typically employed for locating potential corrections in the candidate-generation process. "A lexical-similarity measure between the misspelled string and the candidates" (*e.g.,* the number of editing operations required to transform one string into another) or "a probabilistic estimate of the likelihood of the correction" is then used to rank the candidates. Others, however, notably many probabilistic and neural network techniques, "combine all three subprocesses into one step" by forming a list of dictionary words computed to be 'similar' to a given string, checking whether the top-ranked word is identical to the string, and, if it is not, offering (a sublist of) the list as replacement suggestions.

The accuracy of isolated-word error correction appears to have an upper bound of less than 100%, for even humans would probably have to resort to guessing at the intended correction in our example: "given *isolated* [emphasis ours] misspelled strings", writes Kukich, "it is difficult to rank candidate corrections based on orthographic similarity alone". Furthermore, "regardless of the progress ... made on isolated-word error correction, there will always remain a residual class of errors that is beyond the capacity of those techniques to handle". These are *real-word* errors and the only techniques capable of dealing with them are those making use of *context*.

One way of classifying real-word errors is according to the level of NLP constraints that they violate [Kukich, 1992]. We can distinguish *syntactic* errors (e.g., *I didn't ∗all him at his house because I didn't want to ∗wait other people up*), *semantic* errors (e.g., *Place right leg approximately waist high on a ∗tale or chair and slowly bend forward at waist*), *discourse structure* errors (e.g., *Kukich identified ∗four principal areas of research: nonword error detection, isolated-word error correction, and context-dependent word error correction*), and *pragmatic* errors (e.g., *Our next contestant comes from*

*Manitoba, *France*).[1] "Tools are just beginning to emerge for handling syntactic errors in unrestricted texts", with two approaches being predominant: natural-language parsing and word-level n-gram analysis. Errors from the other three categories, however, are much more difficult to handle, for their detection and correction seemingly requires full-fledged natural language understanding.

Is the problem of real-word error detection and correction a pressing one? According to the few studies concerning the frequency of this kind of error in unrestricted text, the answer is yes. In a "small but insightful" [Kukich, 1992] study, Atwell and Elliott [1987] harvested a sample of 50 errors each from three different sources: manually proofread published texts, essays written by 11- and 12-year-old students, and texts written by ESL speakers. They found the proportions of syntactic and semantic errors (*i.e.,* those belonging to the first two categories above) to be 48%, 64%, and 96%, respectively. Mitton [1987, 1996] analyzed 924 short compositions (10 minutes, mean length 184 words) handwritten by 15-year-old Cambridge secondary school graduands and found 40% of all misspellings to be real-word errors. He distinguished wrong-word, wrong-form, and word-division errors, which accounted for 17%, 9%, and 13%, respectively. Three other "studies of handwritten material", [Wing and Baddeley, 1980, Sterling, 1983, Brooks *et al.*, 1993], which chose to ignore word-division errors, post 26%, 26%, and 29% as the proportions of real-word errors (thus being in nice correspondence with Mitton's 26% (17% + 9%)). "It appears", Mitton [1996] concludes, "that real-word errors account for about a quarter to a third of all spelling errors, perhaps more if you include word-division errors." In fact, since Mitton's interests lay in tracing patterns of true spelling errors (misspellings, slips, and typos), it is likely that his findings too reflect the proportion of only syntactic and semantic errors. Thus, the overall incidence of real-word errors may be even greater. Kukich observes that "increasing use of automatic spelling checkers has probably reduced the number of nonword errors found in some genres of text", thus increasing "the relative

[1] In this classification scheme, non-word errors can be categorized as *lexical* errors.

ratio of real-word errors to nonword errors" in comparison with that indicated by earlier studies. *A fortiori*, misused spelling correctors are bound to introduce additional real-word errors: a user who doesn't have an original reference at hand may be prone to be easily 'convinced' by a spelling checking program to replace the rare *savoy* in *savoy cabbage* with *savory* or even *savvy*; in a different scenario, when offered a list of candidate replacements for the string $*peac$, a careless user may accidentally choose *peach* in place of the intended *peace*.

5.2 Previous Work in Malapropism Correction

Malapropisms are those syntactic and semantic errors that are close to their intended correction in either spelling or sound, yet quite "different and malapropos" [Hirst and St-Onge, 1998] in meaning. Although we are unaware of any relevant findings, intuition tells us that an overwhelming majority of real-word spelling errors from the above two categories will qualify as malapropisms.[2] (In particular, all of our examples above do: $*all \leftrightarrow call$, $*wait \leftrightarrow wake$, $*tale \leftrightarrow table$.)

Hirst and St-Onge [1998; St-Onge, 1995] used their adaptation to WordNet of Morris and Hirst's *Roget's*-based algorithm for constructing lexical chains (Section 4.2.2 in an experiment in the detection and correction of malapropisms. At the heart of the method is the hypothesis that "the more distant a word is semantically from all the other words of a text, the higher the probability is that it is a malapropism" along with the fact that lexical chains are, by definition, "sets of words that are semantically close". Given a text (with non-word errors corrected), St-Onge's program constructs lexical chains between the high-content words. The program then assumes that a (non-compound) word w is a malapropism (and generates an alarm for the user) if it is in a chain by itself (also referred

[2] From [Mitton, 1996]: "It appears that the majority of wrong-word errors arise because the writer makes the wrong choice from a pair of words that look or sound similar or intends to write one but in fact produces another."

to as an *atomic* chain) while there *is* a word w' for which w is a "plausible mistyping" that "would be in a [non-atomic] lexical chain had it appeared in the text instead of w".

To test their algorithm, Hirst and St-Onge randomly selected 500 articles on a variety of topics from two years of the *Wall Street Journal*, in which they then replaced roughly one word in every 200 with a malapropism. They found the experiment's results (which we will touch upon in Section 5.6.2) "encouraging" overall, but suggested that the performance may be improved through the adoption of a better measure of semantic relatedness.[3] It is this suggestion that has, by and large, motivated the research presented in this chapter.

Although Hirst and St-Onge's appears to be the only effort to tackle the problem of detecting and correcting malapropisms specifically, we must mention, even if briefly, the work in context-sensitive spelling correction by Golding and colleagues [Golding and Roth, 1996, Golding and Schabes, 1996]. Both **WinnowS** [Golding and Roth, 1996] and **Tribayes** [Golding and Schabes, 1996] view the task of context-sensitive spelling correction as one of "word disambiguation" [Golding and Roth, 1996]. Ambiguity among words is modeled by *confusion sets*: a confusion set $C = \{w_1, \ldots, w_n\}$ means that each word $w_i \in C$ "could mistakenly be typed" [Golding and Schabes, 1996] when another word $w_j \in C$ was intended; given an occurrence of a word from C in the text, then, the task is to decide, from the context, which $w_k \in C$ was actually intended. The specific techniques of addressing the issue are what distinguishes WinnowS from Tribayes. The former uses a multiplicative weight-updating machine learning algorithm, representing members of confusion sets as *clouds* of "simple and slow neuron-like" [Golding and Roth, 1996] nodes corresponding to context words and collocation features. The latter combines a part-of-speech trigram method and a Bayesian hybrid method [Golding, 1995], both statistical in nature: the trigram method relies on probabilities of part-of-speech sequences and fires

[3] "A lexical chainer that quantifies semantic relations more accurately should enable a higher malapropism detection while decreasing the number of false-alarms" [St-Onge, 1995].

for confusion sets whose members would differ as parts-of-speech when substituted in a given sentence (*e.g.,* {*hear, here*}, {*cite, sight, site*}, and some cases of {*raise, rise*}); the Bayesian hybrid method relies on probabilities of the presence of particular words, as well as collocations and sequences of part-of-speech tags, within a window around a target word and is applied in all the other cases (*e.g.,* for confusion sets like {*country, county*} and (most cases of) {*peace, piece*}).

One advantage of both WinnowS and Tribayes over semantics-heavy methods such as [Hirst and St-Onge, 1998], is that they can handle function-word and low-semantic-content–word errors with apparent ease, simply by considering confusion sets like {*than, then*} and {*to, too*}. Furthermore, they are not restricted to malapropisms: {*amount, number*} is also an example of a perfectly valid confusion set. Their principal drawback, at the moment,[4] is the fact that confusion sets must be known in advance. (In particular, pairs from the list of commonly confused words given as an appendix of the Random House dictionary [Flexner, 1983] were used in Golding *et al.*'s experiments.) Thus the above systems look only for errors that they know about ahead of time, with the process of *detection* essentially reduced to what might be termed *verification*: a word will be checked for being an error only if it belongs to a confusion set; moreover, every occurrence of such a word will undergo an attempt to be *corrected* (*i.e.,* its confusions will be considered in its place every time the word is encountered).

5.3 The New Algorithm

5.3.1 Introductory Remarks

At the onset of the project described below, we intended to pursue two principal objectives:

[4] Golding and Schabes do report having begun investigating the possibility of "acquiring confusion sets (or confusion matrices) automatically".

1. to use the task of malapropism detection and correction as a testbed for a representative subset of measures of semantic relatedness, and

2. to consequently achieve better performance of St-Onge's [1995] system by replacing the original measure rel_{HS} (Section 2.3.2.2) with a measure proven superior in the experiment.

Hence, the original plan was to merely implement additional measures as plug-ins for St-Onge's system and use that system for the experimental comparison. However, as the work progressed, the possibility of additional improvements became apparent, and our perspective changed somewhat. As a result, a new malapropism correction system came into being and was used for the measure-comparison experiments instead of St-Onge's.

The chief deviation from [Hirst and St-Onge, 1998] was that, while adhering to the original underlying idea, *i.e.,* Hirst's conjecture above, we chose to abandon lexical chains, thereby eliminating the overhead associated with their construction and maintenance, and use relatedness computations more directly (*see* Section 5.3.3.5 below). This precipitated other changes, such as the adoption of a bidirectional search for related terms, turning the scope of search into a parameter of the algorithm, and allowing disambiguation to be only partial. Among other, more minor, modifications were augmenting the system with a proper-name recognition engine and addressing the issue of morphological ambiguity.

The following sections, then, present the new algorithm and discuss its particulars.

5.3.2 Algorithm Overview

The pseudocode for the main module of our malapropism corrector is given as Algorithm 5.1.

Processing a given text (`text`) begins with identification and extraction of *valid terms* of maximum length (line 1). A sequence of characters constitutes an instance of a *valid*

Algorithm 5.1 The Core of the Malapropism Corrector

Parameters:

`text` % *the text to be processed*
`distance()` % *the measure of semantic distance to be used in search for relatives*
`threshold` % *the relatedness threshold to be used in search for relatives*
`scope` % *the scope of search for relatives*

1 Break the `text` into tokens; recognize terms.
2 Place all the multiply occurring terms and the compound terms in the `Confirmed` list and the rest in the `Unconfirmed` list.
3 Superimpose a paragraph representation, `Paragraphs[numpars]`.
4 **foreach** term $T_i \in$ `Unconfirmed` **do**
5 **if** ($\exists$ relatives $\{\mathcal{T}_k\} \neq \varnothing$ of T_i (other than itself) within `scope`) **then**
6 Prune T_i's sense list.
7 Move T_i to `Confirmed`.
8 **else if** ($\exists$ alternative lemmas $\{\mathcal{A}_j\} \neq \varnothing$ for T_i) **then**
9 **foreach** term $A_j \in \{\mathcal{A}_j\}$ **do**
10 **if** ($A_j \in$ `Confirmed`) **then**
11 Update A_j's paragraph list.
12 Delete T_i.
13 **leave loop**
14 **else if** ($A_j \in$ `Unconfirmed`) **then**
15 Update A_j's paragraph list.
16 Move A_j to `Confirmed`.
17 Delete T_i.
18 **leave loop**
19 **else if** ($\exists$ relatives $\{\mathcal{T}_l\} \neq \varnothing$ of A_j (other than T_i) within `scope`) **then**
20 Prune A_j's sense list.
21 Insert A_j into `Confirmed`.
22 Delete T_i.
23 **leave loop**
24 **end if**
25 **end foreach**
26 **else if** ($\exists$ spelling variations $\{\mathcal{S}_j\} \neq \varnothing$ of T_i) **then**
27 **foreach** term $S_j \in \{\mathcal{S}_j\}$ **do**
28 **if** (($S_j \in$ `Confirmed`) $\vee$ ($S_j \in$ `Unconfirmed`)
$\vee$ ($\exists$ relatives $\{\mathcal{T}_m\} \neq \varnothing$ of S_j (other than T_i) within `scope`) **then**
29 Add S_j to list $\{\mathcal{C}_n\}$ of candidate replacements of T_i.
30 **end if**
31 **end foreach**
32 **if** ($\{\mathcal{C}_n\} \neq \varnothing$) **then**
33 Raise an alarm.
34 **end if**
35 **end if**
36 **end foreach**

term, or a *valid token*,[5] if it is not on the stop-list, does not denote a named entity, and, in its stemmed form, is present in the system vocabulary (lexicon). Our current implementation uses a stop-list of 221 closed-class and high-frequency words and a Named Entity Recognition engine (*see* Section 5.3.3.2) to weed out high-ambiguity and low-semantic-content words (e.g., *current*, *dozen*, *go*, *must*, *use*, *well*, *1931*) and words, such as names, that are likely to result in spurious connections (e.g., *lotus* as in *Lotus Development Corporation* and *hart* as in *Mr Pete Hart*), and to reduce the number of vocabulary lookups.

A term that has not been invalidated so far is passed to the lookup module, which checks whether the term, in its original form, is present in the system lexicon by itself or as the first component of a phrase. If it is and there are longer phrases, the corresponding token is examined along with its successors in the sentence (both in their original and stemmed form) in an attempt to recognize such a phrase. If the term as it appears in the text cannot be found in the lexicon, dehyphenation and stemming are attempted.

Because, for the reasons mentioned in Section 2.3.1, the semantic distance measures implemented all operate only on nominal entries in WordNet, we use the *noun* portion of WordNet1.5 as the system vocabulary. The morphology (stemming) module employs WordNet1.5 routines to recover lemmas of *nouns* and *verbs*. Thus, inflected verbs occurring in the text are also considered as long as there exists a noun with an identical lemma (e.g., *walked* $\rightarrow$ *walk*, *slept* $\rightarrow$ *sleep*, etc.).

Each non-compound term starts out as a member of the `Unconfirmed` list (*i.e.,* the list of terms that may prove to be malapropos). As the phrase identification process continues, discovering a new instance of a previously identified term results in the term's update (*see* Section 5.3.3.1) and transfer to the `Confirmed` list (*i.e.,* the list of terms

[5] No concensus with respect to the relevant terminology is evident from the Computational Linguistics literature. In our use, *term* denotes what is sometimes referred to as *word type*, while *token* denotes a specific occurrence, or instance, of a *term* in text. Also, when the distinction between *terms* and *tokens* is unimportant (*e.g.,* in discussions concerning semantic distance), we continue to speak of *words* as in the preceding chapters.

whose correctness has been ensured; line 2).

To facilitate efficient access to the physical surroundings (context) of any given word, an array of lists, `Paragraphs[]`, is introduced in line 3. The element `Paragraphs[`i`]` is a list of (pointers to) all the terms that occur in paragraph i.

Once the initial text representation has been constructed, we proceed to the malapropism detection stage. For each originally *unconfirmed* term, the system attempts to find one or more terms occurring in its physical vicinity (as determined by `scope`) that are semantically nearby according to a given `distance` measure (line 5; *see* Section 5.3.3.5 below). If such terms, which we refer to as *relatives*, exist, the current term is regarded as having the intended spelling. The term's sense list (*see* Section 5.3.3.1) is revised (line 6; *see* Section 5.3.3.7) and the term itself is decreed *confirmed* by placement on the `Confirmed` list (line 7).

According to Hirst's conjecture (*see* Section 5.2), if no relatives can be found, our term is likely to be a malapropism. Before proceeding to examining its spelling variations, however, the system attempts to account for a possible case of morphological ambiguity. This is achieved by subjecting the original form of the given term to another bout of stemming. If the process produces one or more lemmas different from the one adopted at first (line 8), e.g., *axis* instead of *ax* for *axes* or *feel* ('an intuitive awareness', etc.) instead of *felt* ('a fabric made of compressed matted animal fibers') for *felt*, every such lemma (encased in a temporary term) is tested for having duplicates in the text (lines 10 and 14) or related terms (within the `scope`; line 19). Passing any one of these tests will serve as a confirmation of the correctness of its surface form, and the first alternative term A_j that does so will replace the original term T_i (and be moved to `Confirmed` if not already there).

If no suitable alternative lemma exists, the suspicion that our term may be a malapropism remains and, in order to further investigate it, we examine the term's spelling variations (line 26; Section 5.3.3.8) in a manner analogous to alternative lemmas (line 28).

```
class Term
{
  char lemma[];
  char original[];
  IndexList senses;
  IndexList paragraphs;
}
```

Figure 5.1: Skeleton of the `Term` data structure.

Namely, if there exist spelling variations that either occur in the text or have relatives within the scope around our term (while the term itself does not), we consider that to be enough evidence that the term is malapropos, and notify the user (line 33).

5.3.3 Details of the Algorithm

5.3.3.1 The `Term` Data Structure

Recognition of the first instance of any term results in the creation of an instance (object) of the data structure `Term`, whose key[6] components are depicted in Figure 5.1. The string `original` contains the form of the first instance of the term as it appears in the text, while `lemma` contains its stemmed version. The field `senses` initially points to the list of all the WordNet synset indices,[7] which may shrink as the computation proceeds (*see* Section 5.3.3.7). Finally, `paragraphs` points to the list of numbers of all the paragraphs in which the term occurs.

The first two fields are used for term identification and generation of replacement candidates. Different occurrences of the same term in a text are recognized through their having the same lemma. However, if the term with the stem *lie* surfaces in the text as *lain*, its spelling variations (Section 5.3.3.8) should include *gain*, *lair*, *loin*, *lawn*, *plain*,

[6] In practice, the addition of a one-bit field to `Term` can obviate both the `Confirmed` and `Unconfirmed` lists, thus streamlining the representation (to consist solely of `Paragraphs[]`). We have chosen to use the two lists in the algorithm description for ease of presentation.

[7] At the heart of the `IndexList` element is an integer `index`; the only other interesting field is `tag`, which is used, for instance, to mark a particular sense (*see* Sections 5.3.3.5 and 5.3.3.7).

etc., and not *die*, *lee*, *life*, *lieu*, and *pie*. Notice that we only need to store the surface form of the first instance in `original`, as spelling variations are never generated for terms that occur in the text more than once.

The last two fields are relied upon in relatedness computations (*see* Section 5.3.3.5). Also, it is the field `paragraphs` that is updated when a new instance of a term is encountered.

5.3.3.2 Named Entities

As we mentioned in Section 5.3.2, our malapropism-correction system, in an attempt to reduce the number of spurious associations, incorporates a module for filtering out proper names. In the current implementation, the module, based on a Lexical Analyzer generously made available to us by Dekang Lin and Nalante Inc., functions as a preprocessor, making a pass through a given text and submitting its output to the rest of the system. Sentence (2), for instance, is thus transformed into (2′), which subsequently undergoes the procedure of valid-term extraction by means of stop-list and vocabulary lookup.

(2) Weather permitting, Mr. Russell commutes every day from his Novato, Calif., home in his single-engine airplane.

(2′) Weather permitting commutes every day from his home in his single-engine airplane .

We will see more examples and some discussion in Section 5.6.1.

5.3.3.3 Compounds

In our special treatment of compounds (line 2), we follow St-Onge's [1995] intuition that the probability of an accidental formation of a multiword compound (phrase) (e.g., *abdominal cavity*, *chief executive officer*, *automated teller machine*, *withdrawal symptom*) is so low that any such phrase can be regarded as confirmed through intra-relatedness.

Having noticed that single-word compounds like *weekend*, *henhouse*, *network*, and *stockbroker* were rather frequently flagged as potential malapropisms (*see* below), we decided to try extending the treatment to this type of compounds. Adding code for rudimentary compound recognition (essentially checking whether a given word can be broken into components that are themselves valid WordNet nouns), however, opened Pandora's box by recognizing 'compounds' such as *genesis (gene+sis)*, *thousand (thou+sand)*, *collapse (col+lapse)*, and *relationship (relation+ship)*. Since the creation of a more sophisticated compound-recognizer appears to be a nontrivial task in itself, the idea was abandoned for the time being.

5.3.3.4 Alternative Lemmas

During trial runs of an earlier, single-lemma, version of our system we noticed words like *allies*, *laws*, *buying*, etc., being flagged as potential malapropisms (for the lack of relatives) but having among their replacement suggestions *ally*, *law*, *buy*, etc., which either have relatives or even occur in the text themselves. The reason that the former words were not recognized as forms of the latter in the first place is that they are present in WordNet as separate entries and hence are recognized without the need for morphing. Sometimes this is perfectly fine (*e.g.,* in one text, *transactions* was intended to mean 'written record' and so was found related to *minutes*), sometimes it doesn't make much difference (*e.g.,* some senses of *dealings* and *dealing* are synonyms and some senses of *years* and *year* are siblings), but sometimes such recognition is detrimental (for instance, in most cases of *ally* and *allies* ('an alliance of nations joining together to fight a common enemy') and *shoe* and *shoes* ('a particular situation')).

These observations led us to address the problem of (lexico-)morphological ambiguity. One obvious solution would be to identify all possible lemmas for a given word during initial tokenization. This, however, would blow up the complexity and proportions of the task, because more synsets (perhaps a conflation of senses) would need to be carried

Algorithm 5.2 Search for Relatives

Parameters:

T_c % *the current term*
`distance()` % *the measure of semantic distance*
`threshold` % *the relatedness threshold*
`scope` % *the size of the search scope (*`scope` $\leq$ `numpars`*)*
`Paragraphs[numpars]` % *the paragraph representation of the text*
T_e % *the 'exception' term*

Result:

set $\{\mathcal{T}_r\}$ of T_c's relatives within scope, or within distance of nearest relative if less then `scope`

1 $\{\mathcal{T}_r\} \leftarrow \varnothing$
2 `back` $\leftarrow T_c^{\S}$ % *the paragraph in which T_c occurs (see footnotes 8 and 9)*
3 `forth` $\leftarrow T_c^{\S}$
4 **while** (`forth` $-$ `back` $\leq$ `scope`) **do**
5 **foreach** term $T_i \in$ ((`Paragraphs[back` mod `numpars]` $\cup$ `Paragraphs[forth` mod `numpars]`) $\setminus T_e$) **do**
6 **if** (`distance`(T_c, T_i) $<$ `threshold`) **then**
7 $\{\mathcal{T}_r\} \leftarrow \{\mathcal{T}_r\} \cup T_i$
8 **end if**
9 **end foreach**
10 **if** ($\{\mathcal{T}_r\} \neq \varnothing$) **then**
11 **return** $\{\mathcal{T}_r\}$
12 **end if**
13 `back` $\leftarrow$ `back` $- 1$
14 `forth` $\leftarrow$ `forth` $+ 1$
15 **end while**
16 **return** $\varnothing$

around and later discriminated among. Wishing to keep the system real-time, we opted for computing alternative lemmas on-demand: *i.e.,* if we cannot find relatives for, say, *allies* or *hijacking*, we apply morphological routines to find *ally* and *hijack* as their alternative lemmas and, if these have duplicates or relatives, we simply substitute them for the originally adopted lemmas (instead of regarding the latter as potential malapropisms and looking for spelling variants).

5.3.3.5 Search for Relatives

Algorithm 5.2 outlines the method used to find terms related to the given term T_c according to the given algorithm for measuring semantic distance `distance`. A pair

of terms is considered related if the semantic distance between them is less then the relatedness threshold `threshold` (*see* line 6).

The idea behind the method is to check every term (other than the 'exception' term T_e) in the vicinity of the given term T_c for being semantically close to T_c while progressively enlarging the vicinity, until either the size of the vicinity exceeds a given limit (`scope`; line 4) or a semantically close term is found (line 10). In the latter case, for the reasons to be explained in Section 5.3.3.7, the procedure does not terminate until it has collected all of the semantically related terms that are within the same physical distance from T_c as the first one discovered.

The size of the search scope `scope` is given in paragraphs, and the text is thought of as a closed circuit, *i.e.,* the last paragraph is taken to precede the first and the first paragraph to follow the last (line 5). Array `Paragraphs[]` (*see* Section 5.3.2) is used to access all the terms occurring in a given paragraph, and the search begins at the[8] paragraph in which T_c occurs (lines 2 and 3).[9]

Looking back at Algorithm 5.1, we can understand the meaning of the final parameter, T_e: when searching for relatives of an original term (Algorithm 5.1, line 5), we do not want to relate it to itself, and, when looking for relatives of an alternative-lemma term (line 19) or a spelling-variation term (line 28), we should ignore the original term.

5.3.3.6 Semantic Distance Between Terms

As was discussed in Chapter 2, measures of semantic distance or relatedness are typically defined on a domain of concepts. In particular, the measures implemented for our malapropism corrector (*see* Section 5.4.1) were meant to operate on nominal concepts of WordNet (represented therein by synsets). As we alluded to in the same chapter, however (*see*, for instance, Section 2.4.1), such measures can be naturally extended to

[8] Being an unconfirmed term, T_c cannot occur in more than one paragraph.

[9] In terms of the `Term` data structure, $T_c^{\S}$ is nothing but the first (and only) element of T_c`.paragraphs`.

operate on words (terms): given a function $\texttt{distance}(s_i, s_j)$ that computes semantic distance between the synsets s_i and s_j (according to some measure), we can define semantic distance between two terms T_l and T_m to be

$$\texttt{distance}(T_l, T_m) = \min_{s_l \in T_l.\texttt{senses}, s_m \in T_m.\texttt{senses}} [\texttt{distance}(s_l, s_m)] \,, \tag{5.1}$$

that is, the distance between their semantically closest senses.

5.3.3.7 Pruning

Referencing Algorithm 5.2 back to Algorithm 5.1, we notice that what the actual relatives of a given term are is unimportant so long as the term has them. (Thus, the search for relatives is described as returning the set $\{\mathcal{T}_r\}$ chiefly for the sake of presentation.) What *may* be useful, on the other hand, is the set $\{\mathbf{S}_i\}$ of the senses of the current term T_c that have resulted in its being considered related to terms within the search scope. In terms of Equation 5.1, these are the synset indices s_l that deliver the minimum to the right-hand side of the equation (*i.e.,* $[\arg RHS]_1$) when T_c takes the place of T_l and T_m ranges over the members of $\{\mathcal{T}_r\}$. Pruning of a term's sense list (referred to in lines 6 and 20 of Algorithm 5.1) then consists in replacing the term's current sense list with the list $\{\mathbf{S}_i\}$ (which is, of course, a sublist of the former).

The main practical reason for pruning is to reduce the number of subsequent computations of concept-distance. That is, according to Algorithm 5.2, after it has been confirmed by virtue of having relatives, a given term T_i will still participate in the term-distance computations *at least* for any unconfirmed term T_j that comes after it in the same paragraph (one paragraph being the smallest scope size). Since any distance computation involving T_i entails concept-distance computations for each of T_i's current senses (*see* Equation 5.1), then, if its sense s_{ik} was not included in $\{\mathbf{S}_i\}$, either it must have not delivered the value of $\texttt{distance}(T_i, T_j)$ or it did, but the value exceeded the related-

ness threshold.[10] In either case, due to the symmetry of `distance`, s_{ik} will not result in anything useful in the computation of `distance`(T_j, T_i) either.

Semantically speaking, sense-list pruning amounts to partial disambiguation. This stand on pruning has actually affected certain design decisions. Namely, as was mentioned in Section 5.3.3.5, if the system discovers the first related term, say, in the paragraph preceding the current token, it will continue scanning the ± 1-paragraph vicinity of the current token (*i.e.,* both the preceding and the following paragraph) just in case there are any other terms within the relatedness threshold. The reason for this is that while we are willing to assume that a term's neighborhood helps resolve the ambiguity of its meaning, we are not willing to put one particular related term from this neighborhood (whose size is measured in paragraphs) above the others (*i.e.,* if instances of two terms related to a given term occur in the same paragraph, their physical distances from the given term are the same and hence their contributions to its disambiguation should be equal).

Note that, aside from the aforementioned savings in computation, pruning can have disambiguation-related effects when it comes to checking relatedness of other terms' spelling variations and of terms surfacing farther from a given term than its nearest relatives.[11]

In the implementation, pruning can be facilitated either by tagging the significant sense of T_c in the process of computing `distance`(T_c, T_i) (*see* footnote 7 on page 83) and preserving the tag if the resulting value is less than the threshold or by adding a field to the `Term` data structure that would contain the significant sense of T_c for each member of $\{\mathcal{T}_r\}$.

[10] That is, mathematically, either $\forall s_{jl} \in T_j.\texttt{senses}\ (\exists s_{im} \in T_i.\texttt{senses} \setminus \{s_{ik}\}\ (\texttt{distance}(s_{im}, s_{jl}) < \texttt{distance}(s_{km}, s_{jl})))$ or $\forall s_{jl} \in T_j.\texttt{senses}\ (\texttt{distance}(s_{km}, s_{jl}) \geq \texttt{distance}(T_i, T_j) \geq \texttt{threshold})$.

[11] In both cases, T_c's sense that has been eliminated could have significance for `distance`(S_j, T_c) or `distance`(T_k, T_c) because neither `distance`(T_c, S_j) nor `distance`(T_c, T_k) has ever been computed.

5.3.3.8 Spelling Variations

Following St-Onge, we use routines from the popular Unix spelling checker **ispell**[12] to generate a list of "near misses" ("words which differ by only a single letter, a missing or extra letter, a pair of transposed letters, or a missing space or hyphen" [`man` page]) for the original form of a given term T_c that has been flagged as a potential malapropism. Those elements of this list that satisfy the validity condition (*see* Section 5.3.2) and are not a morphological variation of T_c's lemma give rise to the spelling-variation terms S_j referred to on lines 26–29 of Algorithm 5.1.

5.3.3.9 Alarms and Related Issues

The exact sequence of actions summarized as "raising an alarm" on line 33 of Algorithm 5.1 should depend on the mode of the program's execution.

It appears sensible to offer the list $\{\mathcal{C}_n\}$ of candidate replacements, perhaps even ranked in order of their semantic proximity to the context. If the session is interactive, the user will then be able to either choose a replacement from the list or type in his/her own. Either action will validate the alarm and should result in replacement of the original term with the correction (and subsequent confirmation (inclusion into `Confirmed`) of the latter). Naturally, the user may alternatively choose to confirm the spelling of the original term, thereby invalidating the alarm. This action should, obviously, result in the confirmation of the original term.[13]

If the program is run in batch-mode, on the other hand, we do not have the luxury of a user's confirmation of either spelling or correction. In this case, there is no foolproof way of discriminating among the replacement candidates, and hence they should not be

[12] International Ispell Version 3.1.08 05/24/94; Copyright © 1983 Pace Willisson; International version Copyright © 1987, 1988, 1990, 1991, 1992, 1993 Geoff Kuenning

[13] If execution speed were at premium, we could opt for raising an alarm as soon as we come across the first spelling variation that passes the test on line 28 of Algorithm 5.1 and having the user either type in a replacement or confirm the original spelling, without offering a list of suggestions.

substituted in. We do, however, have a choice of either removing terms that have been declared as malapropisms from the text representation or leaving them therein. The main effect of selecting the former option is similar to that of pruning (Section 5.3.3.7): savings in computation. If an alarm-bearing term remains in the representation, on the other hand, it is possible that a spelling correction for another term will turn out to be related to it. However, at least within the single-pass sequential processing paradigm, we will not be able to take advantage of this (and, for instance, annul the alarm).[14]

5.4 System Parameters

As is evident from Algorithm 5.1 (Section 5.3.2), there are three principal parameters to the malapropism corrector: the method of measuring semantic distance (`distance`), the relatedness threshold (`threshold`), marking the boundary between the related and unrelated terms, and the scope of search for related terms (`scope`). The following subsections discuss each of these in turn.

5.4.1 Measures of Semantic Distance

Due to time and resource constraints, we were able to implement only a subset of the semantic relatedness measures presented in Chapter 2. We decided to focus our efforts on measures that use WordNet as their knowledge source and admit of a fairly straightforward rendition as functions in a programming language. As a result, six measures were implemented as plug-ins for the malapropism correction system: Hirst and St-Onge's (Section 2.3.2.2), Jiang and Conrath's (Section 2.4.2), Leacock and Chodorow's (Section 2.3.3.3), Lin's (Section 2.4.3), Resnik's (Section 2.4.1), and Sussna's (Section 2.3.3.1).

[14]Similar considerations apply to malapropism-suspects that do not result in an alarm due to their lack of candidate replacements.

5.4.1.1 Distance vs Relatedness

A careful reader may have noticed that, up to this point in our discussion of the algorithm, we have been talking about `distance` despite the fact that four out of the six implemented measures, by design, return a relatedness value. Conceptually, as was alluded to in Section 1.2, this presents no problem thanks to the inverse relation between the two notions: $distance = \text{MAX}(relatedness) - relatedness$ and conversely. Computationally, however, the conversion may at times be difficult to perform: for instance, in Resnik's case, $\text{MAX}(relatedness)$ is ∞.

Therefore, in our actual implementation, we kept the original type of each measure (i.e., *relatedness* or *distance*) and simply associated a different threshold-comparison operator with either type. As a result, in cases of *relatedness* measure, line 6 of Algorithm 5.2 (Section 5.3.3.5) would translate into

if (`relatedness`$(T_c, T_i) >$ `threshold`) **then** .

5.4.1.2 Implementation Notes

Extra-Strong Relations As described in Section 5.3.2, any term occurring more than once in a given text is considered to have the intended spelling without further examination of its context(s). This is identical to Hirst and St-Onge's identification of *extra-strong* relations and is supported, for instance, by Pollock and Zamora's [1983] findings that, with the exception of a handful of frequently misspelled words, misspellings rarely tend to be repeated.[15]

Corpus of Empirical Data Although, in their original experiments, Lin [1997b] and Jiang and Conrath [1997] used SemCor [Miller *et al.*, 1993], a sense-tagged subset of the Brown Corpus, as their corpus of empirical data, we decided to follow Resnik [1995] and

[15] Pollock and Zamora used a 25-million-word corpus of scientific and scholarly writings from chemistry for their analysis.

use the (full and untagged) Brown Corpus (Section 2.4.1) for obtaining the frequency counts of WordNet concepts. While choosing the Brown Corpus over SemCor essentially meant trading accuracy for size, it is our belief that using a non-disambiguated corpus constitutes a more general approach. The availability of disambiguated texts such as SemCor is highly limited, due to the fact that automatic sense-tagging of text remains an open problem of NLP and manual sense-tagging of large corpora is prohibitively labor-intensive. On the other hand, the volume of 'raw' textual data in electronic form has been steadily growing with the development of the Internet. Hence, we may treat the empirical-data corpus as yet another system parameter and use different corpora to fine-tune the performance according to genre or other criteria without additional expenditures.

Hirst and St-Onge's Method We followed St-Onge and Green (personal communication) in setting C to 100 and k to 2 in Equation 2.8. Furthermore, for reasons of efficiency, we adopted Green's modification of Hirst and St-Onge's criteria of **strong** relatedness: cases

> 2. the two words are associated with two different synsets which are connected by a horizontal link

and

> 3. "there is any kind of link at all between a synset associated with each word" but one word is a compound that includes the other

were replaced by

> 2′. the two words are associated with two synsets which are connected by a single link.

Finally, with respect to numerical values, we took our own suggestion (end of Section 2.3.2.2) but differentiated between the two kinds of **strong** relations, corresponding

to 0 links and 1 link between synsets, by giving the weight of $2C$ (200) to the former and $1.5C$ (150) to the latter.[16] As can be seen from Section 5.4.2, this distinction is of no consequence in the framework of the present system. However, it adds an extra grade to the scale of Hirst and St-Onge's measure (which may prove useful in other applications).

Jiang and Conrath's Method Owing to the relative insignificance of values of Equation 2.28 parameters within the best-performance range (Section 2.4.2), we implemented the simplest form of Jiang and Conrath's formula for semantic distance as given by Equation 2.30.

Sussna's Method One of the key constituents of Sussna's measure of semantic distance (Section 2.3.3.1) is the depth d of a given edge (*see* Equation 2.10). Sussna equates it with the depth of the deeper of the edge's end-nodes, where a node's depth is determined as follows. Picture the entire noun network of WordNet as a tree. It is rooted in an extrinsic node posited above the *unique beginners* (*see* Section 2.3.1), and parentage in the tree is by way of any upward relation as well as antonymy. The depths are then "determined recursively as one descends into the tree" [Sussna, 1997]. For a node without an antonym, depth is taken to be one more than the average depth of all of the node's hypernyms and holonyms. Formally,

$$d(c) = \frac{1}{m} \sum_{i=1}^{m} d(\mathrm{par}_i(c)) + 1 \ , \tag{5.2}$$

where c is the given node and the $\mathrm{par}_i(c)$, $1 \leq i \leq m$,are its m parents. If a node does have an antonym, however, "the antonym can be considered as parent and child simultaneously". The depth of such a node is then "defined to be the average of two quantities: one more than the average depth of its parents via non-antonymy links, and

[16] In the light of this scheme, Green's simplification then mathematically means altering the relatedness value of all the pairs of concepts that are one vertical link apart but are not related lexically from $C-1$ to $1.5C$.

two more than the average depth of the parents of its antonym", or

$$d(c) = \frac{1}{2}\left[\left(\frac{1}{m}\sum_{i=1}^{m} d(\mathrm{par}_i(c)) + 1\right) + \left(\frac{1}{n}\sum_{j=1}^{n} d(\mathrm{par}_j(\mathrm{ant}(c))) + 2\right)\right] . \qquad (5.3)$$

Unfortunately, in the course of our attempt at reimplementing Sussna's measure, we ran into two problems which eventually forced us to abandon it.

The first has to do with the number of antonyms. Presumably because it was true of the (earlier) version of WordNet that Sussna worked with, his methodology for the depth calculation presupposes uniqueness of an antonym for a given node. In WordNet1.5, however, this premise no longer holds. For instance, extroversion ('an extroverted disposition; concern with what is outside the self') has both introversion ('an introverted disposition; concern with one's own thoughts and feelings') and ambiversion ('a balanced disposition intermediate between extroversion and introversion') as its antonyms, and disobedience/noncompliance has both conformity/conformation/compliance/abidance ('acting according to certain accepted standards') and obedience.[17]

Formula (5.3) clearly doesn't account for the case of multiple antonyms — but perhaps it could be modified in an intuitive way; for example:

$$d(c) = \frac{1}{2}\left[\left(\frac{1}{m}\sum_{i=1}^{m} d(\mathrm{par}_i(c)) + 1\right) + \left(\frac{1}{s}\sum_{k=1}^{s}\frac{1}{n_k}\sum_{j=1}^{n_k} d(\mathrm{par}_j(\mathrm{ant}_k(c))) + 2\right)\right] . \qquad (5.4)$$

The other problem manifested itself as an infinite loop during an attempted depth computation. The subsequent investigation revealed that, while the WordNet IS-A and PART-OF hierarchies, by themselves, are both proper directed acyclic graphs, the graph resulting from their merging contains cycles (circuits). For instance, burnt sienna ('a reddish-brown pigment produced by roasting sienna') IS-A sienna ('an earth color containing ferric oxides; used as a pigment'), while, at the same time, sienna PART-OF burnt

[17] The second example is actually a little more subtle than the first. The creators of WordNet realized early on that "antonymy is a lexical relation between word forms, not a semantic relation between word meanings" [Miller *et al.*, 1990]. Thus, what we really have in the second example is *disobedience* OPPOSITE-OF *obedience* and *noncompliance* OPPOSITE-OF *compliance*. In Sussna's work, however, there is no indication of its being treated differently from true inter-concept relations like hypernymy or holonymy.

sienna. Similarly, corolla ('the petals of a flower collectively forming an inner floral envelope or layer of the perianth') IS-A petal ('part of the perianth that is usually brightly colored') while petal PART-OF corolla.

At present, we are not certain how Sussna's algorithm should be amended in order to be able to handle situations like these.[18]

5.4.2 Threshold Determination

While, as we argue in Section 6.1.2, a numerical expression of concept proximity is desirable for a number of applications, our task at hand, at its top level, requires merely a binary response: given a pair of terms, we would like to know whether they are related or not.

The simplest way of mapping a continuum (or even a finite number) of (comparable) values onto a set consisting of only two values, say, $\{0, 1\}$, is by selecting a single point (call it a *threshold*) in the original domain and mapping all the points on one side of this threshold to 0 and the rest to 1. This is the approach we decided to take in our work.

Notice that, of the five measures of relatedness ultimately used in the experiments, Hirst and St-Onge's constitutes a special case in that the distinction between related and unrelated concepts is inherent in its definition (*see* Section 2.3.2.2): any pair of **weakly** related concepts is considered unrelated. Hence, Hirst and St-Onge's threshold is 0.

For the remaining four measures, thresholds had to be derived. In order to zero in on a method of doing that, we decided to use the following criteria: first, the threshold for each measure should be linguistically sound; second, the thresholds should be comparable with one another, *i.e.,* the classifications of concepts into related and unrelated produced by the different measure-threshold pairs should agree to the largest extent possible.[19]

[18] Possibilities include calculating depths for each hierarchy separately and then combining (*e.g.,* averaging) the results or even ignoring one of the hierarchies altogether. Following either suggestion, however, would constitute a significant deviation from the original approach.

[19] In the ideal case, then, the measure-threshold pairs would entirely agree with human judgement and with each other.

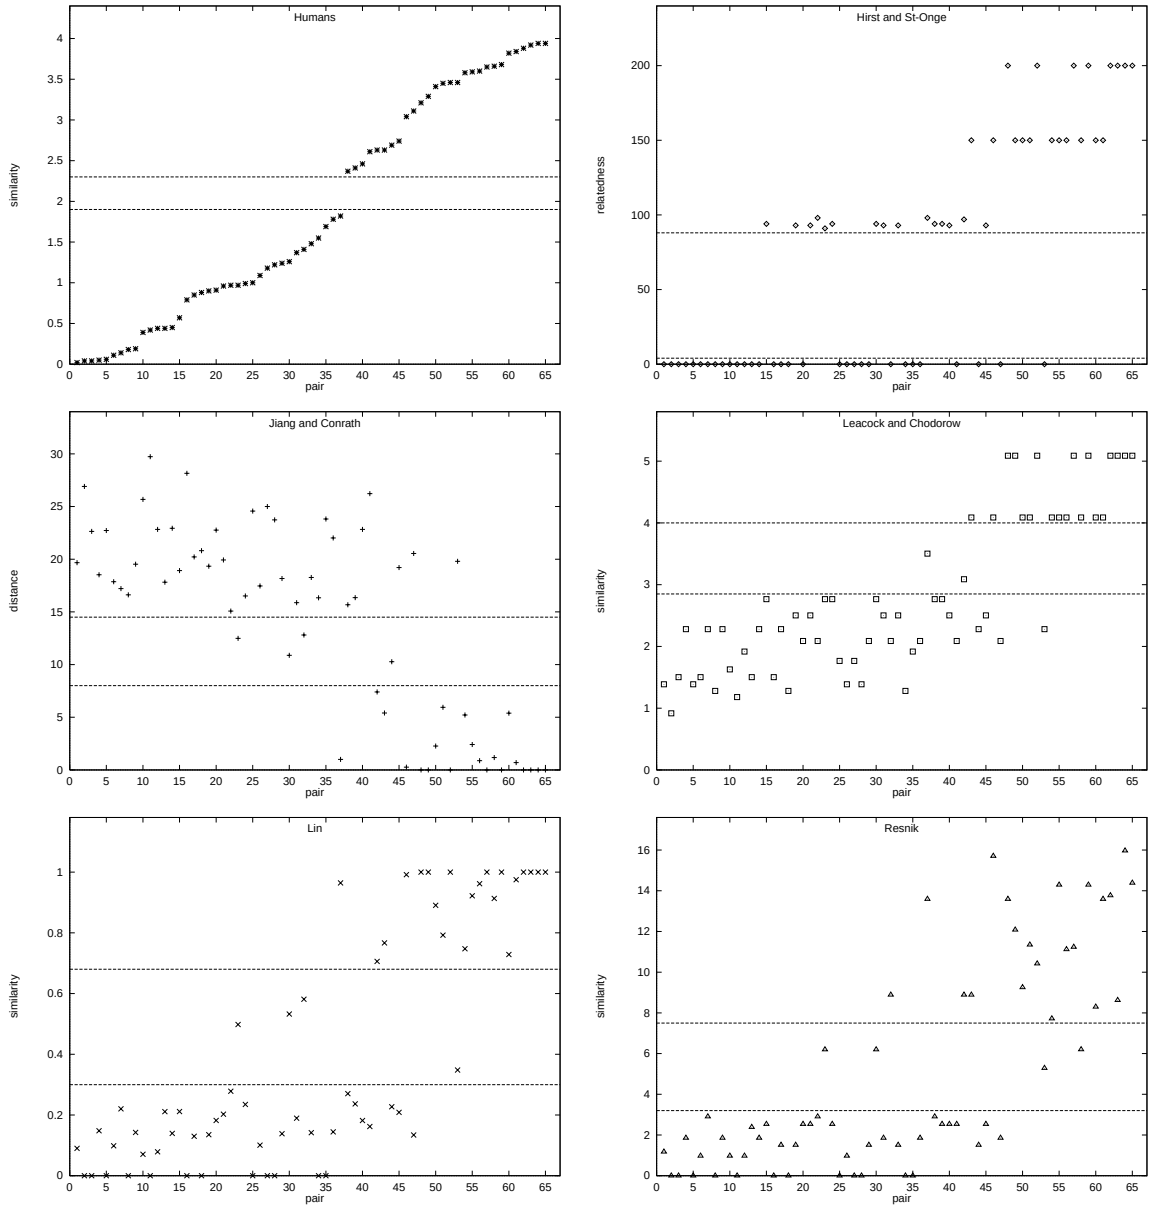

Figure 5.2: Human and computer ratings of the Rubenstein–Goodenough dataset. (Repeated from Chapter 3.)

Reflection upon the above requirements led us to turn to the experimental results of similarity rankings presented in Section 3.3. As we pointed out in the course of analysis of Section 3.3.1, the graphical representation of human similarity-rankings for the Rubenstein–Goodenough dataset (*see* Figure 5.2) exhibits a horizontal band in the vicinity of sim = 2 (the center of the medium-similarity region, separating the pairs *magician–oracle* (37) and *crane–implement* (38)) that contains no points. On the graphs of computed rankings, to these empty regions correspond bands with only a few (2–4) points.

This initial observation makes it reasonable to conclude that the boundary between the related and the unrelated will lie within the identified *uncertainty regions* for all the computational measures.[20] We now have to take a look at each pair in (and about) the uncertainty regions.

Since the pair *crane–rooster* (32) appears in the positive region of Resnik's measure, we shall include it in the positive regions of both Jiang–Conrath and Lin.[21] For Jiang and Conrath's measure, this single manipulation suggests setting the threshold at 13. With such a threshold, both *mound–shore* (23) and *coast–hill* (30) will end up in the Jiang–Conrath positive region, and, by induction, in the positive regions of Lin's and Resnik's.[22] For the latter, this will result in the inclusion of *implement–tool* (58) into the positive region. (The fact that the pair already belongs to the positive regions of the other three measures corroborates the correctness of the last decision.) The pair

[20] We will refer to the regions containing the former two groups of pairs as the *positive* and *negative* region, respectively. Note, that for Jiang and Conrath's measure, which is a distance, the positive region lies below negative.

[21] The reader may notice that the same pair lies in the negative region of the Leacock–Chodorow measure. As was mentioned in Section 3.3.1, however, due to its pronouncedly discrete nature, Leacock–Chodorow has a tendency to blur distinctions. For instance, in this case, it gives *crane–rooster* the same similarity value as it does *automobile–cushion* (22), *bird–woodland* (29), *glass–jewel* (36), and *oracle–sage* (41). All of these lie in the negative regions of the other three measures, but a definite interval away from *crane–rooster*. We therefore take Resnik evidence over that of Leacock–Chodorow.

[22] Here again both pairs can be found in the negative region of the Leacock–Chodorow measure, but, as in the previous case, we choose to ignore this piece of evidence, because of the fact that the pairs *monk–slave* (15), *lad–wizard* (24), *crane–implement* (38), and *brother–lad* (39), all assigned the same similarity value by Leacock–Chodorow's measure, all lie in the negative regions of the other three measures.

serf–slave (53), on the other hand, is found in the negative regions of Leacock–Chodorow and Jiang–Conrath measure, and this suggests that we classify it as unrelated for Lin's and Resnik's as well. These considerations help us arrive at the threshold value of 0.4 for Lin's measure and 6 for Resnik's. Finally, we shall include both pairs *magician–oracle* (37) and *bird–crane* (42) in the positive region of Leacock–Chodorow measure, as they belong to the positive regions of all the other measures. This step will enable us to set the threshold for Leacock and Chodorow's measure to 3.

5.4.3 Search Scope

The final system parameter is the scope of search for related terms.[23]

In Hirst and St-Onge's system (Section 5.2), the search scope was dependent on the type of relation: for **strong** relations, it was limited to 7 sentences, and, for **medium-strong**, to 3 sentences. Also, related-term searches for original terms were backwards only, while for spelling variations they are performed in both directions.

As is evident from the algorithm description, the above rules underwent several modifications for our system. First of all, we decided to measure scope in paragraphs rather than in blocks of sentences, as the paragraph appears to be a more natural unit of segmentation. Second, since four out of our five measures of semantic relatedness do not intrinsically have a division analogous to **medium-strong** *vs* **strong** (and, in effect, we chose to play down this division in case of Hirst and St-Onge's measure as well), we opted for a uniform scope size. Next, searches in all cases were made bidirectional. Finally, as a result of a series of observations, we adopted the *circular model* of text (as mentioned in Section 5.3.3.5): the last paragraph of a text is viewed as preceding the first paragraph and, correspondingly, the first paragraph is viewed as following the last.[24]

[23]This does not include looking for duplicates. Following Hirst and St-Onge, multiple instances of the same term are always recognized throughout the entire text.

[24]One example that motivated our decision is illustrated by the pair *trombone–horn* in the passage quoted in Appendix A: the author mentions *trombone* when talking about Mr. Russell's profession as he begins the narrative (first paragraph); he then comes back to the topic and uses the word *horn* near

Unlike in the problem of threshold determination, where one has to consider a possibly infinite number of candidates, only a small number of feasible alternative sizes of search scope really exist. Hence, we decided to attempt to arrive at an optimum scope(s) by experiment with the following four sizes: 1 (*i.e.,* only the paragraph containing the token in question), 3 (the token's own paragraph plus one paragraph in each direction), 5 (analogous), and the entire text. The result of our experiments are discussed in the following section.

5.5 Performance Evaluation

In order to evaluate the performance of our malapropism corrector and compare the semantic relatedness measures used as plug-ins, the system was fed the 500 articles from the *Wall Street Journal* that were used in Hirst and St-Onge's original experiments (*see* Section 5.2). As in their research, a program was used to replace roughly each 200th valid token (*see* Section 5.3.2) with a malapropism. Articles too small to warrant such a replacement (19 in total) were excluded from consideration. We thus ended up with a corpus of 107,233 valid tokens, 1408 of which were malapropisms.[25]

5.5.1 Some Terminology

In order to adequately describe the criteria used to evaluate the performance of the system, a few terms, due to Hirst and St-Onge, need to be introduced.

- Whenever a token has no relatives within a given scope, it is said to be a *potential malapropism.*

the conclusion (second last paragraph). In general, it is to be expected that concepts introduced at the start of a text will often be recapitulated at the end.

[25] We assume that the original *WSJ*, being carefully edited text, contains essentially no malapropisms of its own.

  - If a potential malapropism has at least one spelling variation that *does* have a relative within the scope (we shall refer to such spelling variations as *candidate replacements*), we say that an *alarm* is raised.

- Whether or not it results in an alarm, a potential malapropism is a *guess*.

  - Those guesses that correspond to actual (introduced) malapropisms are called *correct guesses* and those that do not are *incorrect guesses*.

- If an alarm is triggered by a correct guess, it is a *true alarm*, or a *detected malapropism*. Otherwise, it is a *false alarm*.

- Conceivably, a detected malapropism might or might not have the intended correction (*i.e.,* the original word that was replaced by a malapropism during the generation stage) among its candidate replacements. Finally then, we will call those that do *perfectly detected,* or *corrected,* malapropisms.

5.5.2 Performance Measures

St-Onge [1995] puts forth two *basic hypotheses* which, using the terminology above, can be paraphrased as follows:

(H1) Words flagged as potential malapropisms are (much) more likely to be actual malapropisms than the rest of the valid words are.

and

(H2) Among potential malapropisms, actual malapropisms are (much) more likely to result in an alarm than non-malapropisms are.

These hypotheses motivate the first two measures of algorithm performance presented below.

$Performance_1$ is related to the first hypothesis:

$$performance_1 = \frac{(\frac{\text{number of correct guesses}}{\text{number of malapropisms}})}{(\frac{\text{number of incorrect guesses}}{\text{number of non-malapropisms}})} . \tag{5.5}$$

Qualitatively, $performance_1$ in excess of 1 would mean that actual malapropisms are more likely to be considered to be anomalous in their context (*i.e.,* be flagged as potential malapropisms) than non-malapropisms are.

$Performance_2$ gives us the probability of a correct guess triggering an alarm over that of an incorrect guess triggering one:

$$performance_2 = \frac{(\frac{\text{number of true-alarms}}{\text{number of correct guesses}})}{(\frac{\text{number of false-alarms}}{\text{number of incorrect guesses}})} . \tag{5.6}$$

Thus, hypothesis H2 is true if and only if $performance_2 \gg 1$.

The product of $performance_1$ and $performance_2$ yields the overall *detection-performance* of the algorithm:

$$performance_D = performance_1 \times performance_2 = \frac{(\frac{\text{number of true-alarms}}{\text{number of malapropisms}})}{(\frac{\text{number of false-alarms}}{\text{number of non-malapropisms}})} . \tag{5.7}$$

This expression corresponds to the probability of a malapropism becoming an alarm over that of a non-malapropism. Naturally, we would like this to be greater than 1 also.

Finally, the *correction-performance* of the algorithm is given by the proportion of *perfectly* detected malapropisms among those detected:

$$performance_C = \frac{\text{number of corrected malapropisms}}{\text{number of true alarms}} . \tag{5.8}$$

A visual examination of the four measures laid out above can give rise to a couple of remarks at this point. First, with the exception of correction-performance, the mathematical expressions for the measures involve several (more than two) factors. Therefore, while the end results have nice interpretations, the analysis of the underlying causes and, consequently, attempts to compare the effects of scope and measure may prove rather

involved. Second, one could argue that the user's perception of performance comes only from alarms. Thus, while the performance measures presented can be suitable for testing the overall validity of a malapropism detection and correction algorithm, the user's perspective might be better represented by simpler proportions based on alarms.

These observations led us to augment (and, in part, supersede) St-Onge's evaluation suite with two criteria that constitute the de-facto standard of evaluating retrieval-type tasks: *precision* and *recall*. In the framework of malapropism detection, their general definitions translate into the following:

$$precision = \frac{\text{number of true alarms}}{\text{number of alarms}} \tag{5.9}$$

and

$$recall = \frac{\text{number of true alarms}}{\text{number of malapropisms}} \tag{5.10}$$

We conclude this section by noting that various other quantities of interest may be expressed through the performance measures already presented. In particular, precision and recall values for the task of malapropism *correction* can be obtained by multiplying the corresponding malapropism detection value by the correction performance (*see* Equation 5.8).[26]

[26] For instance,

$$\begin{aligned} precision_C &= \frac{\text{number of corrected malapropisms}}{\text{number of alarms}} \\ &= \frac{\text{number of corrected malapropisms}}{\text{number of true alarms}} \times \frac{\text{number of true alarms}}{\text{number of alarms}} \\ &= performance_C \cdot precision\,. \end{aligned}$$

5.6 Analysis of Results

5.6.1 Some Examples

Before quantifying and analyzing the results of our experiments, we will present a few illustrations to help the reader become more familiar with the terminology introduced in Section 5.5.1 and to demonstrate common situations referred to in the subsequent discussion.

5.6.1.1 Performance on Genuine Malapropisms

We will begin by giving examples of the system's performance on genuine (introduced) malapropisms.

The malapropism *apposition* in sentence (3) was, for all but three measure-scope combinations, *perfectly detected* by the system, i.e., *apposition* was not found to be related to any other term in the search scope *and* its intended correction, *opposition*, was offered as a *candidate replacement*.

(3) But the push in Congress has fallen short in the past, with Mr. Russell's plain talk helping to lead the *apposition*.

In fact, in this particular case, *opposition* was the only candidate replacement, and it was suggested because it occurred elsewhere in the text. But when given Hirst and St-Onge's measure and scope sizes 3, 5, and MAX as the values of its parameters, the system related *apposition* to the term *relationship*[27] found in sentence (4) in the following paragraph and hence it was not even suspected of being a malapropism.

(4) Forewarned, First Interstate, which offers American Express Gold cards and travelers checks, is "reevaluating our *relationship*" with American Express, according

[27] According to WordNet, apposition ('a grammatical relation between a word and a noun phrase that follows') IS-A modification/qualifying/limiting IS-A grammatical relation IS-A linguistic relation IS-A relation SUBSUMES relationship .

to Mr. Hart.

The system's opinions on the status of the malapropism *muss* in sentence (5) varied more widely depending on its parameters.

(5) American Express says only a limited *number* of existing customers will be offered the new card. ... It doesn't know what the *muss* is all about.

Given the entire article as the search scope, Jiang and Conrath's method of measuring semantic distance determined *muss* to be close to the term *state* appearing in sentence (6).

(6) The steeper write-offs, he contends, stem more from "lax" bankruptcy laws and heavy *unemployment* in the major oil-producing *states* than indiscriminate card marketing.

The connection between the two in WordNet is as follows:

muss/mussiness/mess/messiness IS-A disorderliness/disorder IS-A uncleanliness IS-A dirtiness/uncleanness IS-A sanitary condition IS-A condition/status IS-A state .

Hence this example is also a telling illustration of the detrimental role of polysemy in measuring semantic relatedness. The word *state* occurs nine paragraphs later in the text than *muss* so it could not have been even partially disambiguated by the time the latter was being examined. Thus, all of its senses, not just 'the territory occupied by one of the constituent administrative districts of a nation', participated in the distance calculations, and the sense 'the way something is with respect to its main attributes' resulted in an acceptable value of distance.

Narrowing the context in this example did alter the outcome. With the search scope limited to five paragraphs, three paragraphs, or one paragraph (*i.e.,* the paragraph containing *muss* itself plus two, one, or zero paragraphs before and after), the system was

no longer able to relate *muss* to anything with Jiang and Conrath's measure. In each of these cases, however, the term had spelling variations that did have relatives within the scope (in other words, it had *candidate replacements*), such as *mass*, *muds*, *mugs*, and even *mess* (but in the sense 'a large number or amount or extent', in which it was connected to the term *number* highlighted in example (5) above), which resulted in a (true) *alarm*. Furthermore, for the scope sizes of 3 and 5, the intended correction *fuss* was among the candidate replacements, with the term *business* marked as its relative. For the scope size of 1, *fuss* was rejected as a candidate replacement, since *business* occurred in the following paragraph. Thus, *muss* constituted a *detected malapropism* in all three cases and, in the former two, it was *perfectly detected*, or *corrected*.

Other relatedness measures exhibited similar trends with respect to the scope size. For instance, combining Leacock and Chodorow's measure with the scope sizes 3, 5, and MAX resulted in a correction, while combining it with the scope size of 1 only in a detection. Resnik's measure with the entire text as the scope also enabled the system to detect the malapropism perfectly, with the scope of 5 or 3 paragraphs imperfectly, and with the scope of one paragraph the system was not even able to find relatives for spelling variations, hence no alarm was raised, and *muss* was declared merely a *potential malapropism*.

In contrast with the *apposition* example, the malapropism *flaw* (sentence (7)) was not even suspected as such by all but five measure-scope combinations.

(7) Mr. Russell argues that usury *flaw* depressed rates below market *levels* years ago, making current rates seem high.

The Jiang–Conrath, Leacock–Chodorow, and Hirst–St-Onge measures, for instance, all found *flaw* to be related to the term *state* (in the same sense (and sentence) as quoted earlier). The last two measures also related it to *level* and *unemployment* (through *state*). Lin's measure was not able to make for any of the above connections, but it did find *flaw* close enough to the terms *jump* and *fall*, whose instances occur in the preceding

paragraph in the article.[28] When the system was given Resnik's measure with the scope sizes of 3, 5, and MAX and Lin's measure with the scope size 1, however, no relatives were found for *flaw*, while its spelling correction *law* already occurred earlier in the text (where it was confirmed), so the malapropism was perfectly detected. The system with Resnik's measure and scope 1, on the other hand, was only able to detect (offering replacements like *flow* and *flak*), but not correct the malapropism, since, when its earlier occurrence was examined, the term *law* was itself (wrongly) declared a malapropism (and, as a spelling variation, it did not have any other relatives within *flaw*'s context).

We remark that, as in St-Onge's [1995] case, fully automating the process of malapropism generation had the disadvantage of occasionally replacing an original word with a word that was semantically very close to it: e.g., *billion* with *million*, *supplier* with *supplies*, *optimist* with *optimism*, *raise* with *rise*, or even *inquiry* with *enquiry*. While these would be nearly impossible to detect, one could still argue that they nonetheless constitute valid examples of malapropisms (in the sense of mimicking human behavior) and thus should not be excluded from consideration.

5.6.1.2 Performance on Non-malapropisms

We will next look at the system's performance on non-malapropisms (*i.e.,* original, non-substituted, words in the text). Unlike the preceding examples, the default, and desirable, case here should be 'no alarm'. We will therefore mainly focus on the cases where the system misfired.

To a human reader, the word *fox* in passage (8) would hardly seem out of place, even if he or she were not familiar with the idiom.

(8) But Mr. Russell is resolute. "Banks need to realize that there is a *fox* in the

[28] jump/leap ('an abrupt transition') IS-A transition IS-A change/alteration/modification, fall/downfall ('a sudden decline in strength or number or importance') IS-A weakening IS-A transformation/transmutation/shift/qualitative change IS-A change/alteration/modification, and change/alteration/modification SUBSUMES damage/harm/impairment SUBSUMES flaw/defect.

> *henhouse*," he declares. Visa and the 56-year-old Mr. Russell, who enjoys riding a Harley-Davidson *motorcycle*, have collided with *consumers* and Congress before.

After all, *henhouse*s are for cultivating *hen*s, and *hen*s and *fox*es are both animals. Nevertheless, none of the measures were able to make the connection: while, according to some, *fox* is close enough to *hen*, the latter is too far from *henhouse* according to all of the measures. (In fact, it is almost as far from *henhouse* as *fox* is.) Roughly one third of the measure-scope combinations were furthermore unable to relate *fox* to anything else either, but were able to come up with candidate replacements such as *box* (related to *motorcycle*, for both are instrumentality/instrumentation ('an artifact (or system of artifacts) that is instrumental in accomplishing some end')), *fob*, *cox* (related to *general* in sentence (9) which was taken to be a noun), etc., thereby resulting in a *false alarm*.

(9) "He is more vociferous, but his statements probably reflect the *general* thought of the leading card issuers...."

The system run with the remaining combinations marked *fox* as a confirmed term; however, when the relations underlying these decisions were examined, it turned out that, in every single case, an inappropriate sense of *fox* was used. For example, Leacock and Chodorow's measure found *fox* to be related to *hide*, where the latter was an unfortunate nominalization of the identical-lemma verb and the former was interpreted as the pelt of a fox. Hirst and St-Onge's measure connected *fox* to *consumer* by noticing that, when the former means fox/dodger/slyboots, both are persons. An even more exotic sense of the word *fox* was chosen by Jiang and Conrath's and Lin's measures, which were able to relate it to *question*, *response*, and *american*:

> Fox IS-A Algonquin/.../Algonquian language IS-A Amerind/.../American-Indian language IS-A natural language/tongue IS-A language/linguistic communication ('a systematic means of communicating by the use of sounds or conventional symbols') ,

question/interrogative/interrogative sentence IS-A sentence IS-A string of words/.../linguistic string IS-A language/linguistic communication

(and similarly for response/reply/answer), and

American/.../American English IS-A English/English language IS-A West Germanic language ... IS-A Germanic language ... IS-A Indo-European language ... IS-A natural language/tongue .

This example also lets us say a few more words about the named-entity recognition component of the system. All of the sample sentences above have been reproduced as they appear in original documents (except for the malapropism substitutions). After preprocessing by the Named Entity Recognition engine (*see* Section 5.3.3.2), however, passage (8), for instance, would become

(8′) But is resolute . Need to realize that there is a *fox* in the *henhouse* he declares . Visa and the 56-year-old who enjoys riding a *motorcycle* have collided with consumers and Congress before .

(which would be reduced even further during the validation stage). As we can see, we have gotten rid of a couple of noise words, such as *Harley-Davidson*, *Mr*, and *Russell*, the last of which could result in another unwanted connection similar to *fox–consumer*, because it happens to be in the WordNet lexicon with a single sense Russell/.../Bertrand Russell which is subsumed by person/individual/.... However, the transformation has not been perfect. On the one hand, we have lost an occurrence of the term *bank*, which must have been mistaken for a last name (presumably due to its position and frequency); on the other hand, the term *Visa* has not been recognized as a proprietary name (even though *Visa International*, occurring elsewhere in the document, was). Likewise, the term *American Express* was winnowed by the system throughout the document, but not when it surfaced in *American Express Gold cards* — and this is where the term *american* from the very last relation example came from.

69 just checking

The following example was alluded to in Section 5.4.3 where we attempted to motivate the circular model of text. For the scope sizes of 1 and 3, the word *trombone* in sentence (10) occurring in the very first paragraph of the article, was marked as a potential malapropism by the system.

(10) Charles T. Russell used to play *trombone* in Pittsburgh burlesque houses and with big bands in the Southeast.

When the scope was increased to 5, however, the article's second last paragraph, containing sentence (11) became a part of the context, and the Leacock–Chodorow, Resnik, and Hirst–St-Onge measures were able to make the desired connection.

(11) Like scores of musicians, he put down his *horn* when television arrived in the 1950s.

Having decided to investigate the reasons why the other two measures failed to do so, we discovered that the probability of concept trombone is zero, as there are no occurrences of the word *trombone* (or its sole subordinate *sackbut*) in the Brown Corpus (which was used to derive the probabilities; *see* Section 5.4.1.2). Since the expression for Lin's similarity contains the (negative) logarithm of this probability in its denominator (Equation 2.34, Section 2.4.3) and the expression for Jiang and Conrath's distance contains the same term as a part of a sum (Equation 2.30, Section 2.4.2), the value of the former, for trombone and horn, came out infinitely small (*i.e.,* essentially zero) and that of the latter infinitely large. Obviously, the values of the Leacock–Chodorow or Hirst–St-Onge measures were not affected as they are edge-based (*see* Section 2.4.2), but nor was that of Resnik's, since it only makes use of the lowest superordinate of the two concepts (brass), which in this case had a non-zero probability.

As the reader may have noticed, of the five measures participating in the experiments, only Hirst and St-Onge's can take advantage of WordNet relations other than IS-A. Our

final example is intended to demonstrate how this distinction can affect the behavior of the system. Let us come back, one last time, to sentence (12).

(12) "Banks need to realize that there is a *fox* in the *henhouse*," he declares.

As we have seen earlier, none of the relatedness measures were able to see the connection between *henhouse* and *fox*. It should therefore be expected that the former be declared a potential malapropism. In effect, this is what happened with every measure except Hirst and St-Onge's, which, when given to the system, enabled it to detect a relationship between *henhouse* and the word *ceiling* from sentence (13) since

> henhouse/. . . /chicken coop IS-A farm building IS-A building/edifice HAS-A room HAS-A ceiling .

(13) As in past years, Congress is currently considering imposing rate *ceilings*, and some consumer groups think such a law would be an appropriate response to Mr. Russell's recent harangue.

5.6.2 St-Onge's Performance Measures

A summary of the results with respect to several performance criteria introduced in Hirst and St-Onge's [1998] original malapropism detection and correction research is given in Table 5.1 and Figures 5.3 and 5.4.

For the reasons discussed in Section 5.5.2, we will restrict our analysis to merely making a couple of remarks. All the values of $performance_1$, $performance_2$, and $performance_D$ *are* greater than 1, as desired. Figures within each category are similar overall in magnitude and compare fairly well with Hirst and St-Onge's original results.[30] The corrective

[29] The results given under the heading *chains*, here and onwards, are those of Hirst and St-Onge's *lexical-chain*-based system (Section 5.2).

[30] It should be noted that all of the figures in Table 5.1 are but single data-points, as opposed to statistical means of some sort. Thus, we cannot make any definite judgements concerning their comparison, any apparent trends (*e.g.,* with respect to scope), or the like. In order to do so, we would have

Table 5.1: St-Onge's performance values.[29]

Measure	Scope	$performance_1$	$performance_2$	$performance_D$	$performance_C$
rel_{HS}	1	4.24201	1.95027	8.27306	93.1034

chains	N/A	4.47	2.46	11.0	87.9093

power of the system appears reasonably high, exceeding that of the chain-based system in almost three-quarters of the cases.

5.6.3 Precision and Recall

We conducted random sampling of transformed output of our system to end up with 30 values of recall and precision for each of the 5×4 measure-scope combinations. Their corresponding mean values are given in Table 5.2.

As we can see, the values of precision range roughly between 7% and 25% and the

to gather multiple data-points and subject them to a statistical analysis. However, it is precisely the complexity of the expressions for $performance_1$, $performance_2$, and $performance_D$ that would make this task problematic.

[31] The figures in the last row of the table, and, consequently, the corresponding points in the graphs following, are *not* based on simple random sampling and are given here for a coarse comparison only (*cf* footnote 4, page 129).

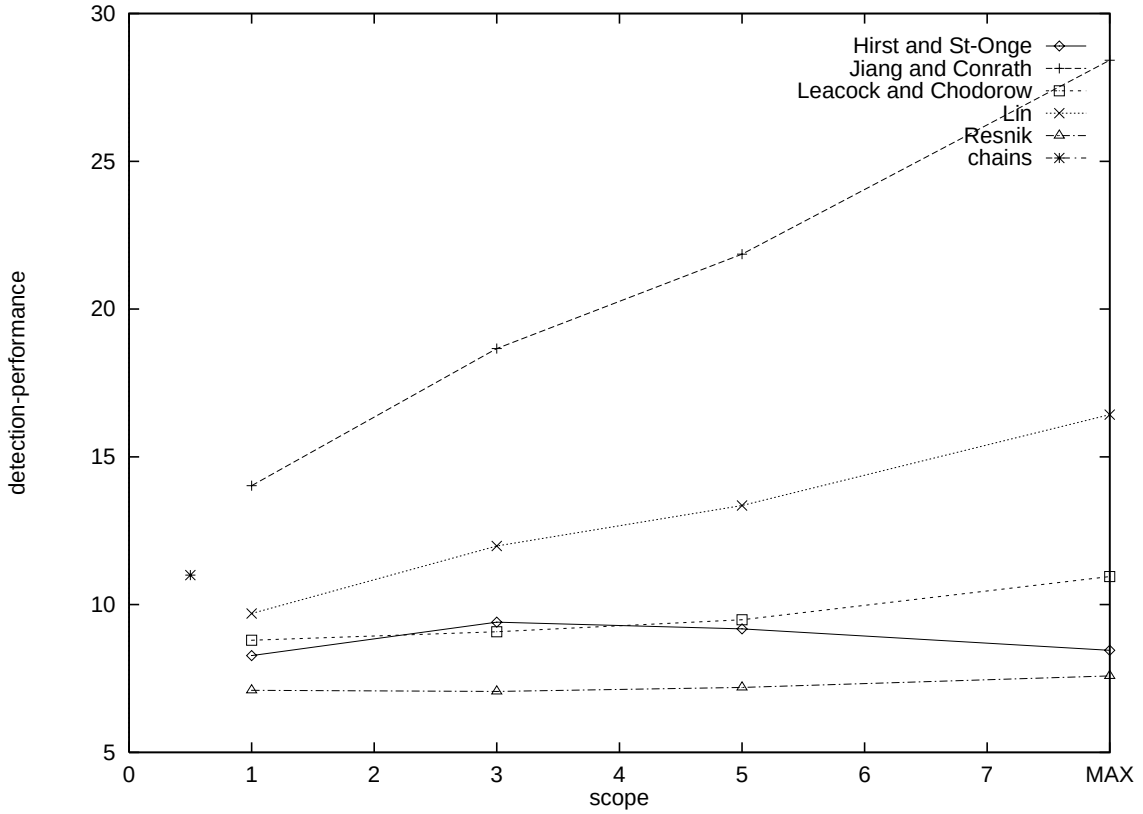

Figure 5.3: A graphical summary of detection-performance as a function of measure and scope.

values of recall between 5% and 60%. Even though the absolute values of the lower ends of both intervals do not look inordinately impressive, they can be shown to be significantly ($p < 0.001$) better than chance.[32]

As was stated in the introductory part of the chapter, malapropism detection was chosen *both* as a framework for comparison of several techniques of measuring semantic relatedness between words *and* as a research project in applied natural language processing. Hence, when analyzing the recall and precision as functions of the search scope and

[32]For the "chance" method, precision coincides with the probability of a randomly generated alarm being a malapropism. By the frequency principle, this equals the proportion of malapropisms in the text, which, in our case, is 1408/107233, or approximately 1.31%. Under the usual additional assumption that the number of raised alarms should be equal to the number of malapropisms, the value of recall is

$$\frac{\text{number of true alarms}}{\text{number of malapropisms}} = \frac{\text{number of true-alarms}}{\text{number of alarms}} \cdot \frac{\text{number of alarms}}{\text{number of malapropisms}},$$

or the same as precision.

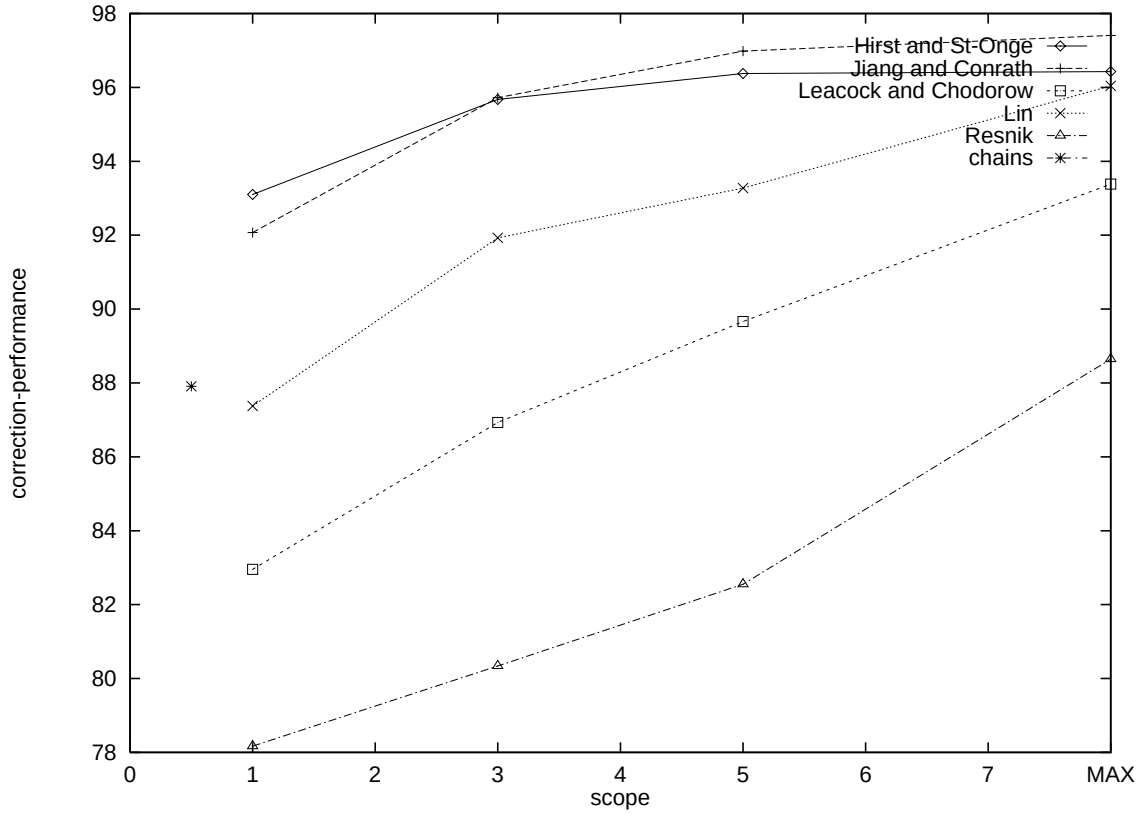

Figure 5.4: A graphical summary of correction-performance as a function of measure and scope.

the method of determining semantic relatedness, we seek answers to questions such as these:

- What measure and which scope yield the best recall and the best precision?
- What combination of the two parameters yields the best recall and the best precision?
- How do the measures rank relative to each other with respect to recall and precision?

Figure 5.5, providing a graphical representation of the recall data from Table 5.2, suggests a tendency of the recall to decrease as the scope increases.

A look back at Algorithm 5.1 (Section 5.3.2) proves this tendency to be an intuitive one. Remember that a word is flagged as a malapropism if it does not have any relatives

Table 5.2: Sample means for precision and recall, based on SRS's of size 30.[31]

Measure	Scope	*precision*	*recall*
rel_{HS}	1	0.0967	0.2633
rel_{HS}	3	0.1022	0.1489
rel_{HS}	5	0.1167	0.0956
rel_{HS}	MAX	0.1022	0.0556
dist_{JC}	1	0.1433	0.4622
dist_{JC}	3	0.2044	0.3389
dist_{JC}	5	0.2167	0.2922
dist_{JC}	MAX	0.2411	0.1700
sim_{LC}	1	0.1156	0.6033
sim_{LC}	3	0.1178	0.4711
sim_{LC}	5	0.1089	0.4233
sim_{LC}	MAX	0.1322	0.3067
sim_{L}	1	0.0956	0.5156
sim_{L}	3	0.1456	0.3933
sim_{L}	5	0.1667	0.3000
sim_{L}	MAX	0.1722	0.1756
sim_{R}	1	0.0900	0.5500
sim_{R}	3	0.0722	0.5278
sim_{R}	5	0.0944	0.4589
sim_{R}	MAX	0.0922	0.3167
chains	N/A	0.1254	0.2818

within the search scope while at least one of its spelling variations does. Naturally, one would expect the number of tokens related to a given token to grow with scope (in a large enough corpus, *e.g.,* a book, we can arguably find a relative for just about any word), thus resulting in the reduction of the total number of alarms and, with it, the number of true-alarms. Using analysis of variance, we were able to prove that, with the exception of Resnik's measure for scopes 1 and 3, this trend is indeed statistically significant ($p < 0.05$). Thus, for any given measure, the scope of 1 results in the best recall value.[33]

The question of the best method, in terms of recall, of determining semantic closeness, as well as the more general question of relative ordering of the methods, unfortunately,

[33]For Resnik's distance determination method, this value is statistically indistinguishable ($p > 0.15$) from that obtained with the scope of 3, but it still exceeds those resulting from the remaining two values of scope.

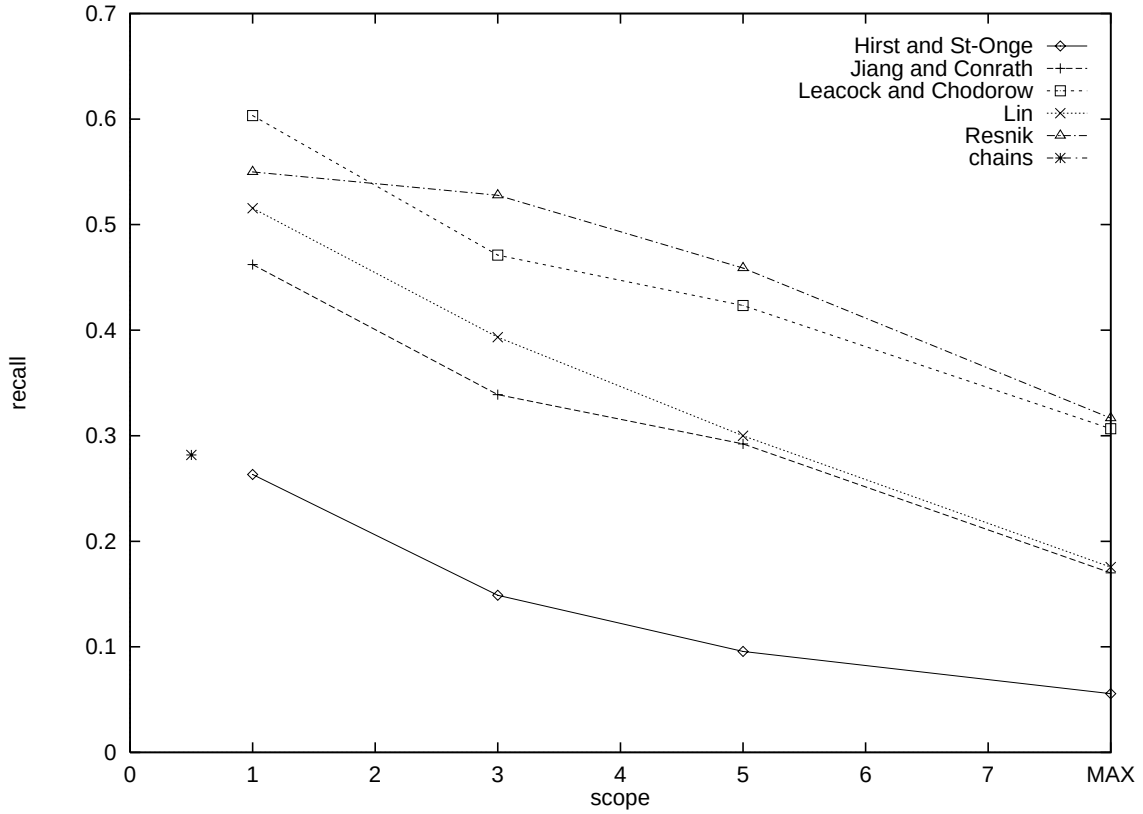

Figure 5.5: Sample means for recall, by measure and scope.

does not have such a clear answer. As Figure 5.5 indicates (and as statistical analysis confirms), in some cases (*e.g.,* Resnik and Leacock–Chodorow) the measure-mean recalls[34] have values too close to one another, and, even if they do not, a nontrivial amount of interaction between the two factors, scope and measure, is present. In particular, the measure-means of the two measures whose graphs are located near the top of Figure 5.5, Resnik's and Leacock and Chodorow's, are statistically identical ($p > 0.27$), as are their mean recalls for each of the two largest values of scope. For scope 1, however, Leacock and Chodorow's measure performs better than Resnik's, and for scope 3, the roles are reversed ($p < 0.01$). Leacock and Chodorow's measure does, however, consistently outperform Lin's and Jiang and Conrath's measures ($p < 0.001$), which, in turn, outperform Hirst and St-Onge's measure for all values of scope ($p < 0.001$). Finally, the difference

[34]Each measure m can be thought of as having four mean recalls μ_{ms} associated with it in the population: one for each value of scope. The *measure-mean* recall will then be $\mu_m = \sum_s \mu_{ms}/4$.

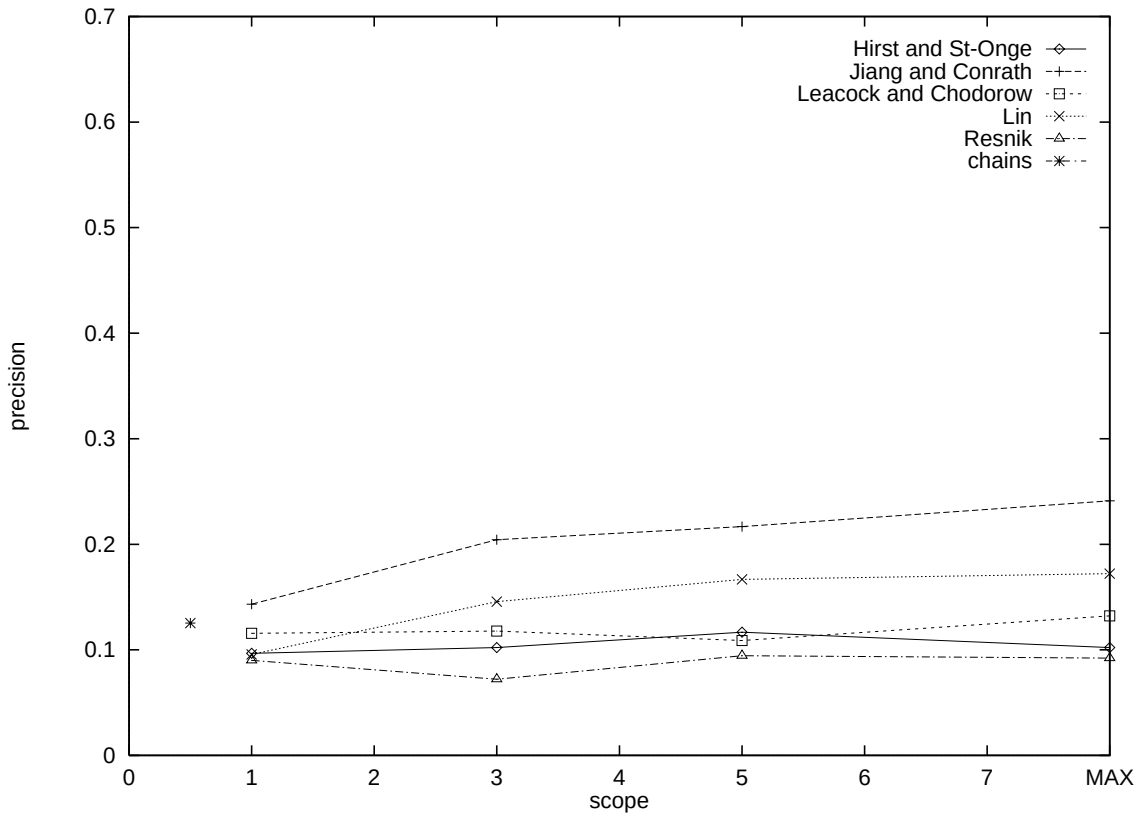

Figure 5.6: Sample means for precision, by measure and scope.

between Lin's and Jiang and Contrath's measure is statistically significant ($p < 0.05$) for the values 1 and 3 of the search scope and is statistically negligible ($p > 0.35$) for the remaining two values of scope. It thus follows that the winning measure-scope combination for recall is Leacock and Chodorow's measure with the scope value of 1.

The picture for precision turns out to be not nearly as uniform as that for recall. Even visually (*see* Figure 5.6), the graphs in the upper portion of the plot (Jiang and Conrath's and Lin's measure) appear to behave differently from those in the lower portion (Leacock and Chodorow's, Hirst and St-Onge's, and Resnik's): the former two seem to tend upwards as the scope increases, while the latter seem to fluctuate about some average value.

Again, a recollection of the main ideas behind the core algorithm can help us interpret this behavior. Firstly, as we mentioned a moment ago, the overall number of alarms (the denominator in formula for precision; *see* Equation 5.9) should decrease as the scope

increases, due to the fact that fewer tokens will be flagged as potential malapropisms. On the other hand, once a token has been identified as a potential malapropism, it has a higher chance of resulting in an alarm, and a true-alarm in particular, the larger the scope, for its (intended) spelling correction is more likely to turn out to have related tokens.

Statistical analysis reveals that, for Leacock and Chodorow's, Hirst and St-Onge's, and Resnik's measure, the search scope does not constitute a statistically significant factor (*i.e.,* their graphs are actually flat). The main qualitative difference between these measures and the Jiang–Conrath and Lin is the fact that, for the latter two, the variation in precision *is* significant ($p < 0.001$) for the values 1 and 3 of the scope (after which, however, the graphs also level off). Overall, scope 3 can therefore be considered as resulting in the best value of precision.

Analyses of variance and contrasts show that Jiang and Conrath's measure performs best in terms of precision. Lin's measure comes second with its precision mean for scope 1 being statistically indistinguishable ($p > 0.19$) from those of the remaining three measures, but the precision means corresponding to scope 3 (and larger) exceeding theirs. Finally, the measure-means of Leacock and Chodorow's and Hirst and St-Onge's measures are statistically indistinguishable (marginally, $p = 0.067$), but both exceed the mean of Resnik's measure. From these observations, we can conclude that Jiang and Conrath's measure with the search scope of 3 delivers the highest mean precision.

Lastly, we address the question of the best overall performance, *i.e.,* optimum recall *and* precision. Note that the superiority of smaller values of scope for recall and the statistical insignificance of larger values of scope for precision narrow the discussion to the scope sizes of 1 and 3. In fact, for the Leacock–Chodorow and Hirst–St-Onge measures, the scope size of 1 is the unique choice. For Resnik's measure, we can also pick scope 3 — and obtain statistically equivalent performance. Since the precision values for scope 1 of all the three measures are statistically indiscernible, the relative ranking of

Table 5.3: Relative ranking of the Leacock–Chodorow, Resnik, and Hirst–St-Onge measures.

Rank	Measure	Scope	*precision*	*recall*
$A1$	sim_{LC}	1	9–11%	60%
$A2$	sim_{R}	1	9–11%	50–55%
$A3$	rel_{HS}	1	9–11%	26%

Table 5.4: Relative ranking of the Jiang–Conrath and Lin measures.

Rank	Measure	Scope	*precision*	*recall*
Bi	dist_{JC}	1	14–15%	46%
$B(i+1)$	sim_{L}	3	14–15%	39%
Bj	dist_{JC}	3	20%	34%
Bk	sim_{L}	1	9–11%	50–55%

the measure-scope combinations in question (we will call them Group A) is determined entirely by recall and hence looks as in Table 5.3.[35]

The situation with Jiang and Conrath's and Lin's measures, on the other hand, is somewhat more complicated. For both, there is a statistically significant tradeoff between recall and precision, *i.e.,* by expanding the search scope from 1 to 3 paragraphs, we can gain approximately 5–6% in precision but lose approximately 12–13% in recall — and vice versa. Furthermore, the relative positions of the two measures are opposite for precision and recall. The state of affairs in this group (let us refer to it as Group B) can be summarized by Table 5.4.

A quick comparison of Tables 5.3 and 5.4 will reveal that Lin's measure with scope 1 (the last entry in the second table) in effect belongs to group A, where it ties Resnik's

[35] The precision and recall values in this and the following table are based on sample means from Table 5.2. All the numbers have been rounded to the nearest integer. When a measure has statistically indistinguishable neighbors with respect to a parameter, an appropriate range is given instead of a single number for that parameter.

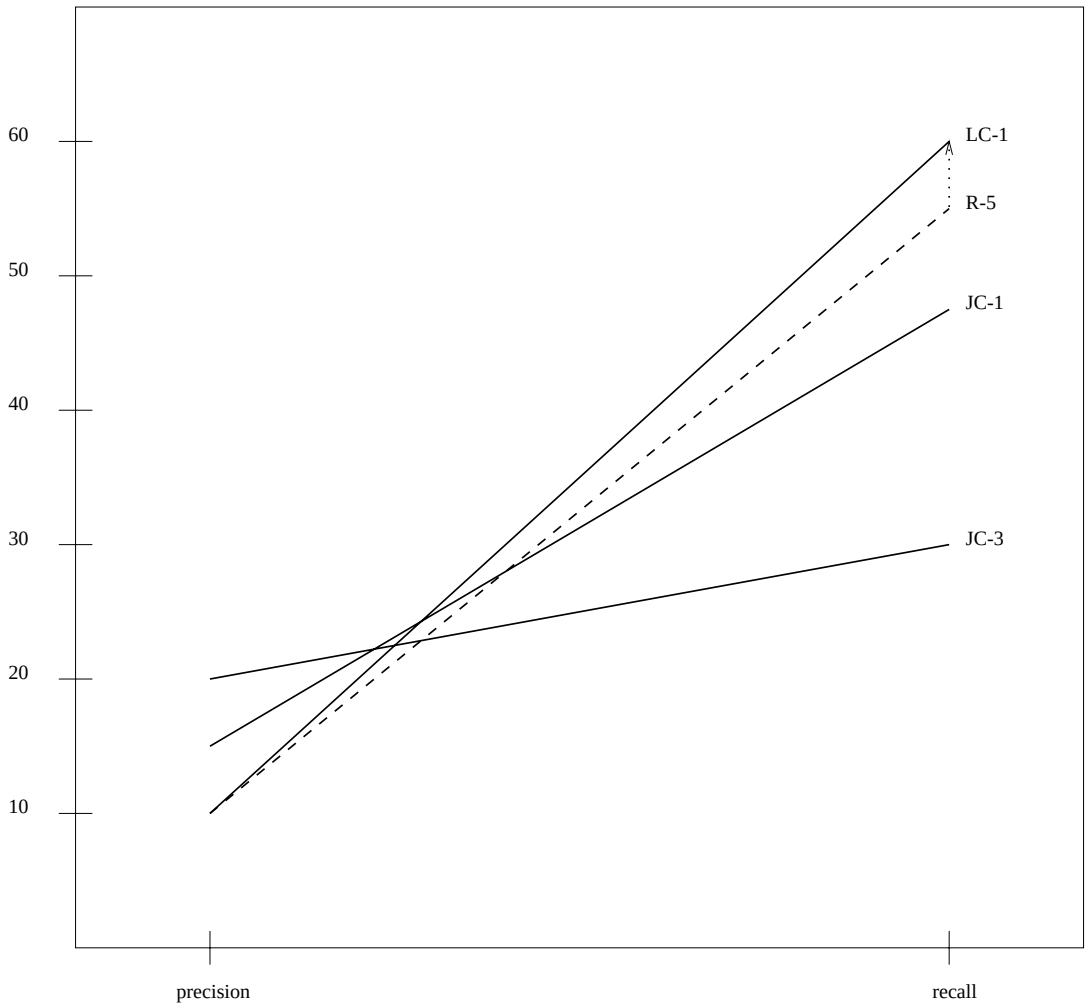

Figure 5.7: The extremum parameter-combinations with respect to precision-recall trade-off.

measure with scope 1 (both their mean precision and recall values are statistically identical; *see* above).

This last observation leaves us with three combinations, Leacock and Chodorow's measure with scope 1, Jiang and Conrath's measure with scope 1, and Jiang and Conrath's measure with scope 3 (we will refer to them collectively as group C), that cannot be ranked relative to one another: for any two of these, one surpasses the other in precision but falls short in recall. These combinations (depicted graphically in Figure 5.7) can be thought of as local (dual) extrema or states of equilibrium: any of the other seventeen measure-scope combinations is statistically inferior to (more precisely, not better

than) one of these three (*e.g.,* Resnik's measure with scope 5 yields statistically the same precision but poorer recall than Leacock and Chodorow's with scope 1; *see* Figure 5.7), and an attempt at a maximum improvement of one performance criterion of a member of group C (*e.g.,* recall of Jiang and Conrath's with scope 1) with a minimum sacrifice in the other criterion (precision) will result in adopting another member of the group (Leacock and Chodorow's with scope 1; note that we cannot adopt Resnik's with scope 5, because if we did, the gain in recall would not be maximal).

Hence, from the user's perspective, Leacock and Chodorow's measure with the search scope of 1 should be used if recall is at a premium; Jiang and Conrath's measure with the scope of 3 should be used if the highest possible (mean) precision is desired; finally, Jiang and Conrath's measure with scope 1 should be used for an optimum midway performance.

Chapter 6

Conclusion

6.1 Measuring Semantic Relatedness

6.1.1 Summary

Evaluating the degree of semantic proximity between a pair of lexically expressed concepts is a problem with a long history in philosophy, psychology, and artificial intelligence, which pervades much of computational linguistics, and many different perspectives on which have been proposed.

The objective of this work has been to take stock of some computational methods of measuring semantic relatedness that have appeared within the last decade or so, along with their applications, offer some insights into the question of their relative comparison, and, finally, suggest directions for future research in the area.

To this end, we have presented a survey of 13 approaches, classifying them by the principal knowledge-source they deploy. These have included dictionary- and thesaurus-based approaches, approaches using a semantic network (such as MeSH or WordNet), as well as approaches combining multiple knowledge sources (in particular, a *knowledge-rich* source such as a thesaurus and a *knowledge-poor* source such as corpus statistics).

A variety of recently developed applications of measures of semantic relatedness have

also been presented, from resolution of word-sense ambiguity to discourse segmentation to word prediction in speech and text recognition.

Given the diversity and the sheer number of existing ways to gauge semantic relatedness, the question of their (comparative) assessment naturally arises. While human relatedness-ratings of concept pairs should, by definition, be regarded as the standard against which ratings produced by computational measures are to be evaluated, obtaining a sizeable set of reliable, subject-independent judgements proves highly problematic. As a result, all of the attempts to perform an evaluation of this sort that we are aware of [Resnik, 1995, Jiang and Conrath, 1997, Lin, 1998] have been based on a set of no more than 30 pairs [Miller and Charles, 1991]. For the sake of compatibility and research continuity, we followed up on these attempts, extending the evaluation to more measures and a larger set of 65 pairs [Rubenstein and Goodenough, 1965]. For our main evaluation, however, we opted to perform a comparison within the framework of a particular NLP application.

We selected six proposals, all using WordNet as their (semantic) knowledge source, of which we were able to successfully (re)implement five: Hirst and St-Onge's, Jiang and Conrath's, Leacock and Chodorow's, Lin's, and Resnik's, thus representing *simple-path-length*, *scaled-path-length*, and *hybrid* semantic-network approaches. These five measures then participated in a word-pair relatedness rating exercise, the principal quantitative outcome of which was coefficients of correlation with human ratings, as well as in a malapropism-correction experiment (*see* below).

6.1.2 Conclusions and Future Directions

The figures of correlation with human judgements do not conclusively point to the superiority of any one particular method. In fact, our findings seem to refute or, at least, weaken some of the previous claims. We should, however, reiterate our assertion that even 65 pairs constitute too small a test set to be taken too seriously. Our first suggestion

for future work then pertains more to research in psycholinguistics than in computational linguistics: larger collections of human ratings need to be compiled and cognitive processes involved in making relatedness judgements by humans need to be further studied.

As will be discussed in more detail in the following section, our test NLP-application was a system for *detecting and correcting malapropisms*. Deviating from the previous practice [St-Onge, 1995, Hirst and St-Onge, 1998], we have focused on *precision* and *recall* as its performance indicators. No measure, or measure-scope combination, has been found optimal in terms of both of these simultaneously (*e.g.,* dist_{JC} excels in precision, while sim_{LC} and sim_{R} deliver best recall). We have, however, shown the question of relative ranking to have a parsimonious solution, with twenty combinations reduced to three optimal.

Despite being a step forward, the current evaluation scheme still allows us to draw only limited inferences concerning the 'goodness' of the measures of semantic relatedness plugged into the system. For instance, Resnik's good recall and poor precision suggest that the reason for the former is merely a large total number of generated alarms. Unfortunately, this by itself does not tell us much about the behavior of the measure, *e.g.,* whether it 'overrelates' or 'underrelates' (since, for a word to result in an alarm, the word must be declared unrelated to its context, while its spelling variation must be found to have a relative). Thus, our second suggestion for future research is to develop other performance-assessment methodologies for the malapropism detection task that would be more 'transparent' with respect to the semantic distance measure used, and to seek other NLP tasks that may inherently possess such transparency.

Of the five measures participating in our experiments, Hirst and St-Onge's was the only one taking into account relationships other than IS-A. As its creators suspected, however, and as our findings confirmed, its relative simplicity impairs its performance. Nevertheless, our intuition dictates that *relatedness* measures of reasonable power should yield better results in any tasks relying on context, and malapropism detection and cor-

rection in particular, than measures of *similarity* alone. Hence, our next recommendation is that efforts be directed towards developing approaches that would exploit more fully the gamut of semantic relationships already available in resources such as WordNet.[1] These efforts can build on some of the existing research [St-Onge, 1995, Sussna, 1997, Jiang and Conrath, 1997], which has suggested, for instance, that local network density, depth of a node, strength of a link, and link type and direction should be among the factors to be given consideration. A possible first step in this direction may be to attempt transplanting measures defined on the IS-A hierarchy to other hierarchies, such as PART-OF and the verb IS-A hierarchy.

In fact, we can go one step further and remove the restriction of being *semantic* from the set of relations we propose to be considered.[2] That is, even from our preliminary investigation, it is safe to say that the future belongs to hybrid methods.

An important milestone in improving the quality of computational assessment of semantic relatedness should be identification and incorporation of additional sources of linguistic knowledge such as domain-specific thesauri, statistical word usage information, etc. [Morris and Hirst, 1991], as well as merging of those already in active use. In addition to the initiatives of Resnik, Lin, and Jiang and Conrath, we should mention recent work by Tokunaga *et al.* [1997] and Fujii *et al.* [1997]. Carrying out this program will also help alleviate the problem of part-of-speech restrictions presently imposed on a number of measures by their principal knowledge sources.

Incidentally, the paradigm of merging can probably also be applied to measures themselves. That is, we could form a new measure rel_{New} by combining several existing ones

[1] The emphasis on IS-A in the current research is less surprising if we realize that the relationship is the cornerstone of any dictionary that follows Aristotelian principles: IS-A is the relationship that holds between a headword and its genus [Guthrie *et al.*, 1996]. *However,* it is the other relations that make differentia possible.

[2] The distinction between *semantic* and *non-semantic* has not been firmly established. Kozima and Furugori [1993], for instance, speak of *paradigmatic* relations ("how the words are associated with each other") and *syntagmatic* relations ("how the words are arranged in sequential texts"). Our use of terminology is similar, although we would like to include unary statistical relationships, such as corpus frequency, etc., in the non-semantic category.

$\text{rel}_{\text{Old1}}, \ldots, \text{rel}_{\text{OldN}}$. As a general case, our new measure can be viewed as returning a vector whose components correspond to the relatedness values of its constituent measures. How such vectors are manipulated, *i.e.,* the precise manner in which the constituent measures are combined, might vary (and might even ultimately depend on an application): to determine whether the pair c_1, c_2 is more closely related than c_3, c_4, we could compare the norms of $\text{rel}_{\text{New}}(c_1, c_2)$ and $\text{rel}_{\text{New}}(c_3, c_4)$, or simply see whether a majority of $\text{rel}_{\text{New}}(c_1, c_2)$'s coordinates have larger values than their $\text{rel}_{\text{New}}(c_3, c_4)$'s counterparts (essentially letting the component measures $\text{rel}_{\text{Old1}}, \ldots, \text{rel}_{\text{OldN}}$ 'vote'; *cf* Leacock and Chodorow's simultaneous use of two measures, Section 4.1.3, page 53), or adopt another strategy.

A related issue is whether measures of semantic relatedness or distance should be quantitative (*i.e.,* returning a numerical expression indicative of the strength of relatedness) or qualitative (*i.e.,* giving a, say, binary response, such as *related/unrelated*). We do insist that measures returning a numerical value are more useful than those merely giving a binary response. First, it is feasible to go from the former to the latter, as we have demonstrated in Section 5.4.2, but not vice versa. Second, many applications can make effective use of numerical expressions of distance (to see, for instance, which of a number of concepts is *closest* to a given one; *cf* ranking of candidate corrections discussed in the next section). Lastly, as we saw in Chapter 3, a range of values should allow for a more comprehensive assessment of measures.

Finally, recall that this report has zeroed in on measures of semantic relatedness between the most elementary units: lexemes. However, a fair amount of work, most notably in the fields of Information Retrieval and Extraction, has been devoted to determining relatedness between larger textual units: phrases, sentences, or even entire texts. In a typical IR approach (*e.g.,* the *vector space model* [Salton, 1989], "one of the most successful approaches" according to Green [1997b]), a text (document) is represented by a vector whose elements correspond to the terms used in the text and are indicative of

the term's relative frequency; the (semantic) distance between a pair of texts is then computed geometrically. There thus appears to exist a considerable gap between lexeme-relatedness measures, as discussed in this report, and commonly used text-relatedness measures: while the latter do indeed start with lexemes, lexical *equivalence*, instead of lexical *semantic relatedness*, is used at the lexeme level — and an altogether different methodology is used to go from there to the text level.

The efforts of Green (Section 4.3.2), Rada and colleagues (Section 4.5.1), and Richardson and Smeaton (Section 4.5.2) are examples of attempts to bridge this gap. However, they address only the first problem above. What we would also like to see is methods of computing relatedness between texts that more closely parallel (or extend) methods of computing relatedness between words (perhaps, by virtue of both being derived from the same general principle). We hence propose that in the design of future measures of semantic relatedness between lexemes, consideration should be given to the question of their extensibility to larger textual units. Of the work known to us, perhaps that of Lin [1997a] and Jiang [1998] afford precedents, but the task overall remains a challenge.

6.2 Detection and Correction of Malapropisms

6.2.1 Summary

Although originally conceived primarily as a framework for *application-specific evaluation* (*see* previous section), our excursion into detecting and correcting malapropisms gradually developed into a project in its own right. Following up on the work of Hirst and St-Onge [1998], we introduced a sufficient number of modifications to their algorithm and implementation for the new malapropism corrector described in Chapter 5 to be regarded as a distinct system.

The new system still relies on Hirst's principle that if a word appears *out of* context and is a plausible mistyping for another word that *fits* into the context, it is likely to be a

malapropism. Unlike its predecessor, however, our system avoids the overhead associated with persistent segmentation of context. Instead, the context is viewed merely as a bag of words (whose size is a parameter of execution; *see* below). Verifying whether a word fits into its context then amounts to computing the word's semantic relatedness to every other word in the bag and checking whether any of these exceed a threshold.

The adoption of this model motivated a number of other changes: bidirectional scanning of context, paragraph-based context boundaries, partial, less committing, disambiguation, etc. Lower-level modifications included augmenting the system with a proper-name recognition engine, addressing the issue of morphological ambiguity, and improving the strategy for replacement-candidate generation.

We evaluated the performance of our malapropism detection and correction system with five different plug-in measures of semantic distance (*see* Section 6.1) and four different sizes of context, or search scope[3]: 1, 3, or 5 paragraphs surrounding a target word, and the entire text. For each of the 20 combinations, the program was run on a set of 481 *Wall Street Jounal* articles, in which one in roughly every 200 words had been replaced with a malapropism (and which were large enough to warrant at least one such replacement).

6.2.2 Conclusions and Future Directions

As we reported in Section 6.1.2, no single measure-scope combination has been found to deliver simultaneously the best precision and recall. Of the twenty combinations, however, our system outperformed St-Onge's [1995] in terms of precision for seven, in terms of recall for 14, and in terms of both for six.[4]

A couple of interesting observations have been made about the effect of the context size

[3]Here 'search' refers to the search for related words, which is performed only inside a context.

[4]Unfortunately, we cannot provide any statistical support for these comparisons, for, whereas our precision and recall figures are actually *means* obtained through random sampling of output, St-Onge's are but *overall proportions*.

on the system performance. Although intuition suggests that precision should increase and recall should decrease as the size of context increases, only the latter tendency has turned out to be statistically significant for the measures that took part in our experiments (with a minor exception; refer to Section 5.6.3 for details): the difference in precision was substantial only for the context sizes of 1 and 3 paragraphs and only for two out of the five measures. Thus, our findings point towards overall optimality of smaller scopes.

It should be reiterated here that the search methodology employed in St-Onge's [1995] original system differed from ours. In particular, the search scope was measured in sentences and varied according to the type of connection sought (*e.g.,* the entire text for the *extra-strong*, ± 7 sentences for the *strong*, and ± 3 for the *medium-strong*). In order to keep the framework for all of the measures in our experiments uniform, this custom-tailored scheme had to be replaced. As a result, the performance figures for our system using Hirst and St-Onge's measure appear[5] lower than those of St-Onge's system. Hence, while we believe that our view of context *is* both more principled and universally applicable, additional investigation may be in order.

Another algorithm parameter that may require further work is the relatedness threshold (Section 5.4.2). While, by virtue of the design of Hirst and St-Onge's measure, this was not an issue in their system, when adapting the other four measures to use in our task, we had to select a point in their ranges that would mark the boundary between the *related* and the *unrelated*. This was done by examining the rankings of Rubenstein and Goodenough's pairs produced by the measures in our experiment of Chapter 3 against those of human judges and against each other. As we have mentioned, however, the reliability of inductions made on the basis of this dataset may be questionable due to its size. Thus, we propose that alternative ways of deriving thresholds be explored, such as using pairs from the same thesaural category [Lin, 1997b] or even brute-force experimentation

[5] *See* footnote 4, page 129

with various values of thresholds as a system parameter.

This work has demonstrated the overall significance of the `measure` parameter in our algorithm. All of the representatives of the class of hybrid measures that we have worked with (and for whose superiority we have argued in Section 6.1.2), on the other hand, have an additional *sub*parameter: the corpus for deriving concept frequencies. Thus, when using such measures as plug-ins, varying the frequency corpus according to the text submitted for malapropism correction, *e.g.,* obtaining genre-specific frequency counts — from a proofread newswire corpus for a newspaper article, from an edited novel for a story, etc. — may be another way to improve performance.

Because of the central role of the relatedness computations in our system, most limitations that a given measure of relatedness possesses are 'inherited' by the system. An example of such a limitation is the part-of-speech restriction: as we mentioned in Section 6.1.2, all of the measures that we have worked with are defined on nominal concepts only. To mitigate the severity of this restriction somewhat, we decided to treat as a noun anything that looks like one, either as is or after stemming. For instance, the adjective *drunk* in *drunk driver* will be taken to be a noun; likewise, the verb *drank* will be transformed into *drink*, which, again, is present in the noun lexicon and so will be considered a noun in searches for relatives. While the first example appears quite reasonable, many will argue that *drinking* is a better nominalization of *drank* than *drink* is. A more sophisticated nominalization mechanism (paired, for instance, with the *alternative-lemma* facility; *see* Section 5.3.3.4) may also become a performance-improving factor.

The handling of compound words is yet another avenue for investigation and possible improvement. As reported in Section 5.3.3.3, our simple-minded attempt to extend the special treatment of multiword compounds (confirmation by default) to the single-word case misfired: along with *network* and *stockbroker*, terms like *thousand* and *relationship* were identified as compounds. Incorporating the knowledge of common suffixes, such as *-ship*, as well as modifying the confirmation strategy (for instance, to confirm only those

compounds one or more of whose components have relatives, e.g., *henhouse* since *hen* is related to *fox* occurring nearby) may constitute a good starting point.

Kukich [1992] partitions the task of word-error correction into three subtasks: "(1) **detection of an error**; (2) **generation of candidate corrections**; and (3) **ranking of candidate corrections**". Due to our system's role as a testbed in relatedness experiments, in this work we ended up focusing on malapropism *detection*. It is therefore worth emphasizing here that the system has been designed also with a view to malapropism *correction*. Recall (Section 5.3.2) that a crucial step in deciding whether a *potential malapropism* is a malapropism indeed is coming up with its spelling variations that would fit into the context. This automatically takes care of the second step in Kukich's breakdown. One can then imagine that, during an interactive session, the list of all such spelling variations (*candidate replacements*) can be offered to the user, perhaps even without the need for ranking. In the setting of fully-automatic spelling correction, on the other hand, choosing the best candidate, to be substituted into the text, is essential. At present, this is an open chapter in our implementation. A strategy that meshes most naturally with the existing algorithm is to rank the candidates according to their proximity to the context: *e.g.,* the relatedness value with the context word closest semantically or physically. In our preliminary experiments, the intended correction was found among the candidate replacements for about 78–97% of the detected malapropisms (approximately 83%, 92%, and 96% for the three optimal measure-scope combinations). However, no 'best-first' statistics have been collected so far. Addressing issues more-immediately related to the *corrective* capacity of our system should prove to be another interesting direction for future research.

Appendix A

Sample Text With Introduced Malapropisms

Below is the text of one of the 481 *Wall Street Journal* articles,[1] (automatically) altered to include four malapropisms, that were submitted to our malapropism corrector. The malapropisms are italicized and their intended corrections (*i.e.,* the words appearing in the text originally) are given immediately next to them in square brackets.

A.1 Text

Charles T. Russell used to play trombone in Pittsburgh burlesque houses and with big bands in the Southeast. He gave it up for banking, but he still knows how to attract a crowd.

Mr. Russell, the president of Visa International, a bank-owned credit-card association, recently urged members to consider halting sales of American Express Co. services in retaliation for the financial-service giant's recent decision to begin offering a new cut-rate credit card.

[1]Copyright © 1987, 1988, 1989 Dow Jones Inc.; from *Association for Computational Linguistics Data Collection Initiative CD-ROM 1* (September 1991)

Consumer groups denounced the plea as an illegal restraint of trade, and Congress is considering an inquiry. But Mr. Russell is resolute. "Banks need to realize that there is a fox in the henhouse," he declares. Visa and the 56-year-old Mr. Russell, who enjoys riding a Harley-Davidson motorcycle, have collided with consumers and Congress before. Critics have long alleged that Visa member banks and other card issuers inflate interest rates. As in past years, Congress is currently considering imposing rate ceilings, and some consumer groups think such a law would be an appropriate response to Mr. Russell's recent harangue.

But the push in Congress has fallen short in the past, with Mr. Russell's plain talk helping to lead the *apposition* [opposition]. "He is more vociferous, but his statements probably reflect the general thought of the leading card issuers," says Pete Hart, a First Interstate Bancorp executive vice president.

Forewarned, First Interstate, which offers American Express Gold cards and travelers checks, is "reevaluating our relationship" with American Express, according to Mr. Hart. Nothing rash is planned, he says, but the new card — Optima — is "without question an intrusion into our business."

American Express and the banks are used to being allies rather than adversaries. American Express cards generally don't offer revolving credit, and banks have marketed them alongside their Visa and MasterCard cards, which do.

But Optima will compete head-on. The card will cost $15 a year, in addition to the $45 that American Express charges for its regular card. But it will extend 13.5% credit. The average Visa card also carries a $15 annual fee, but it has a stiffer 17.5% rate, and several big banks charge even more.

American Express says only a limited number of existing customers will be offered the new card. It doesn't expect to issue many more than two million of them by 1990, compared with about 100 million current Visa card holders. It doesn't know what the *muss* [fuss] is all about.

"We are not basically in the credit business," says an American Express spokesman. "We're going after a select market."

But the elite group that American Express is targeting has been a major source of bank credit card earnings. Banks also believe that the American Express estimates are too modest, and some fear a plastic rate war.

"They aren't going to fail," says Mr. Russell. "I don't admire their ethics, but I certainly respect their knowledge." He thinks American Express is misleading consumers, arguing that the Optima rate is closer to 18% when the tie-in with the regular card is considered.

The flap comes at a time when Visa and its members have few other reasons to complain. There are 22% more Visa card holders world-wide than there were two years ago. The group, which furnishes members with new products, system support and other services, is developing computerized cards and new links with automated teller machines. For the banks, credit cards have been a growing source of profits, although tax changes and a growing consumer debt load portend possibly slower future growth.

In orchestrating Visa's expansion, Mr. Russell has hit a few *prong* [wrong] notes with bankers and competitors. Two years ago, he led the opposition against a merger proposal from rival MasterCard, an idea that some bank issuers of both cards thought would cut costs for them and consumers.

Mr. Russell says that the benefits were overrated and that a merger raises possible antitrust problems. Instead, he has backed joint efforts, but some question his interest in cooperating. Visa and MasterCard have been studying a national network to process retail store debit card transactions. Last fall, however, Visa agreed to manage a large similar operation in California, and some MasterCard officials worried that the joint venture had been doomed. Mr. Russell denies this.

His comments about American Express also have some precedent. Last summer, as part of a campaign to blunt another budding competitor, Visa encouraged members to

refuse to honor Sears, Roebuck & Co.'s Discover card in their automated teller machines.

Along the way, critics believe consumers have been cheated. Card rates haven't fallen nearly as sharply as other interest rates since 1980. Current rates also reflect a jump in write-offs of bad credit card loans, which some banks have brought upon themselves through aggressive marketing.

Mr. Russell argues that usury *flaw* [law] depressed rates below market levels years ago, making current rates seem high. He also says critics ignore administrative costs in their rate attacks. The steeper write-offs, he contends, stem more from "lax" bankruptcy laws and heavy unemployment in the major oil-producing states than indiscriminate card marketing.

While Mr. Russell faces possible congressional and Justice Department investigations into his American Express comments, he says Visa welcomes the attention. "We've nothing to hide, never had," adds the executive, who joined Visa in 1971.

Like scores of musicians, he put down his horn when television arrived in the 1950s. While hunting for a music-store job one day in 1953, a rainstorm forced him to take cover at a branch of what is now PNC Financial Corp. The bank hired him as a collector in its installment loan department. He married a former Pittsburgh radio singer who he used to back up in the band.

Weather permitting, Mr. Russell commutes every day from his Novato, Calif., home in his single-engine airplane. The 20-minute flight helps him forget his troubles. "You can't think about anything else when you're flying," he says. "When I fly home, I don't have a problem anymore."
